BUREAU OF MINES

MINERAL FACTS AND PROBLEMS

1965 edition

By Staff, Bureau of Mines

UNITED STATES DEPARTMENT OF THE INTERIOR
Stewart L. Udall, Secretary

BUREAU OF MINES
Frank C. Memmott, Acting Director

Created in 1849, the Department of the Interior—a Department of Conservation—is concerned with the management, conservation, and development of the Nation's water, fish, wildlife, mineral, forest, and park and recreational resources. It also has major responsibilities for Indian and Territorial affairs.

As the Nation's principal conservation agency, the Department works to assure that nonrenewable resources are developed and used wisely, that park and recreational resources are conserved for the future, and that renewable resources make their full contribution to the progress, prosperity, and security of the United States—now and in the future.

This publication has been cataloged as follows:

U.S. *Bureau of Mines.*

Mineral facts and problems, 1965. [Washington] U.S. Dept. of the Interior, Bureau of Mines, 1965.

1113 p. illus. (*Its* Bulletin 630)

1. Mines and mineral resources—U.S. 2. Mineral industries—U.S. I. Title. (Series)

TN23.U4 no. 630 622.06173

U.S. Dept. of the Int. Library.

Washington, D.C., 20402 - Price $6.75 (Cloth Bound)

Foreword

This edition of Mineral Facts and Problems marks the second revision of this widely used reference work. Events have shown that the 5-year interval between editions was well chosen. For many commodities there have been significant shifts in the past 5 years in the world supply-demand position and the production-consumption pattern, resulting both from political and social changes and from advances in science and technology. Despite such major shifts for some commodities, much of the background information presented in the 1960 edition of Mineral Facts and Problems remains pertinent. Hence, substantial portions of the carefully prepared and reviewed material from the previous edition remain unchanged in this edition.

The initial edition of Mineral Facts and Problems, published early in 1956, was an outgrowth of a Bureau of Mines commodity program statement series. The statements, revised periodically to reflect the rapidly changing positions of individual commodities in relation to national demands, provided broad basic and background information from which the Bureau could generate and evaluate ideas for mineral resource development and research investigations. This orderly presentation of mineral information proved useful to other Government organizations, commercial analysts, and educators and students. The Bureau hopes that this edition, Bulletin 630, also will prove as worthwhile a reference and as helpful in understanding and attacking the problems encountered in developing world mineral resources to meet mankind's material needs.

Like its predecessors, this edition represents the work of Bureau specialists—but it depends heavily on information from industry and reviews by critics in both industry and Government for which the Bureau is deeply appreciative. Technical editing of the volume was carried out by Paul Yopes and statistical editing by Kathleen J. D'Amico, both of the Division of Minerals.

PAUL ZINNER
Assistant Director, Mineral Resource Development

INTRODUCTION

By Charles W. Merrill [1]

THE INDUSTRIAL strength and the security of the United States require an adequate, dependable, and continuing supply of raw materials, of which minerals constitute an indispensable segment. With an expanding population, a rising standard of living, and the instability inherent in a constantly changing international situation, the mineral supply outlook is a major national concern.

Structures, roads, and machines are built largely of mineral products; the energy to heat the structures and to power the machines is derived mostly from minerals; agricultural output is sustained with the aid of mineral fertilizers; and the Nation's economic and military security both are founded ultimately on its ability to obtain and utilize essential metals, nonmetals, and mineral fuels.

Mineral supply presents certain problems that are not common to raw materials derived from vegetable and animal sources. Minerals as mined are a one-time crop, whereas the products of agriculture, grazing land, forests, and fisheries continue to be available indefinitely under proper husbandry. Nevertheless, with minerals the possibilities of discovery and the potential inherent in an advancing technology frequently assure the replenishment of depleted reserves. For example, proved recoverable reserves of petroleum in the United States have remained for many years at about 12 times the annual rate of production, despite increasing output. This maintenance of the reserve level has resulted both from discovery of new oil pools and from improved techniques that make possible higher ultimate recovery from known deposits. Likewise, the ore reserves for many metals have been sustained by improved technology that has made it profitable to mine material of lower and lower grade.

Reclamation is an important factor in extending mineral supply. For example, although the gasoline powering an automobile and the lead added to it are consumed beyond reclamation, the lead that makes up much of the same automobile's battery has an extended life because about 85 percent of all lead in such batteries is reclaimed and used again.

To assure a future supply of minerals, the facts about minerals must be ascertained. The mineral problems of today must be identified, and those of tomorrow anticipated. Preparation must be made to attack any impediment to meeting the Nation's mineral requirements—by prospecting for new ore bodies, by research to find improved extractive, processing, and utilization methods, and by making abundant resources substitute effectively for those that are scarce. In short, all available knowledge, foresight, energy, and wisdom must be enlisted to assure the present generation, and those that are to follow, a mineral-resource base on which the United States can continue to build.

MINERAL PROBLEMS

The problems reported constitute obstacles to achievement of major objectives of industry and Government. These objectives are (1) wise production and utilization of U.S. mineral resources, (2) discovery and development of new sources of mineral supply, (3) maintenance of mineral reserves and stocks at adequate levels, (4) fostering a producing and processing industrial capacity large and flexible enough to exploit effectively the domestic mineral resources consonant with all foreseen requirements, and (5) assurance of access to foreign mineral supply to supplement domestic output as needed.

In facing the problems likely to be encountered in the pursuit of these broad objectives, five areas require development and analysis.

[1] Chief, Division of Minerals.

APPRAISAL OF MINERAL POSITION

Major decisions in industrial development and expansion, foreign affairs, international trade, defense, and many other areas frequently require reliable and comprehensive information on the Nation's mineral position. Government agencies charged with conducting U.S. foreign affairs, as well as those charged with procuring materials for defense and other domestic requirements, must know the country's mineral position. The Congress also depends on objective, authentic information so that its legislative decisions may be based on facts. Perhaps most important is an informed private industry, because it is the source of many major decisions involving minerals.

DEVELOPMENT OF SUBMARGINAL RESOURCES

Many deposits in the United States contain such a small percentage of the desired metal or mineral, or are so difficult to treat with present methods, that exploitation would not be profitable. Such deposits are classified as submarginal resources. If technologic history can be accepted as a guide, some of these deposits will be mined when the need becomes great enough or when new technologies make their extraction economically feasible. Some mineral commodities now supplied by importation occur domestically in submarginal deposits so large that the United States could become self-sufficient if cheaper production methods could be devised or if the price of the commodity rose.

The United States undoubtedly contains many submarginal deposits not yet discovered, or at least not delineated. There has been little commercial incentive to search for them or to develop those found in the course of other activities. Nevertheless, a demonstration of very large quantities of material, even if presumably of submarginal quality, is a powerful incentive to private enterprise to attempt commercial development. The early phases of research in submarginal resources often fall to Government, but privately financed organizations frequently undertake such development long before profitable operation can be assured. An example of this type of resource is the oil shale in Colorado and neighboring States, assaying 10 gallons or more per ton, that would yield an estimated 2 trillion barrels of oil if all of it now known could be processed.

POSSIBLE NEW OR WIDER USES FOR ABUNDANT RESOURCES

The United States has large deposits of mineral raw materials for which comparatively little use has been found but which may have applications that are yet to be discovered, for example, before World War II sea water, brines, magnesite, and dolomite, now used as sources of magnesium, were little used. Means that would expand the use of the metals or minerals in such deposits could relieve a serious drain on materials now in short supply that are required in some products and processes. Outstanding examples of plentiful but almost unused resources with promising possibilities are high-alumina clay and anorthosite, raw materials for production of aluminum, and vast reserves of lignite and peat as sources of energy. Furthermore, if commercial application for an abundant but little-used material were devised and demonstrated, a firm foundation would be laid for a new industrial enterprise. Titanium and helium are examples of resources that for many years were in the little-used category.

ALTERNATES

Development of substitutes is one way to improve the mineral position of the United States. Metals, minerals, and mineral fuels in ample supply can be substituted, under certain conditions, for those in scant supply. The maintenance of the German war machine during World War II on liquid fuels synthesized from coal is a spectacular example of substitution in time of stringency. In the United States the increasing substitution of aluminum for tin in tubes and foil has replaced an imported and relatively scarce metal with one in abundant domestic supply. The use, where practicable, of noncoking coals for steam generation in lieu of scarcer fuels that have important and singular use characteristics represents wise substitution. Each substitution of a plentiful mineral for a scarce one strengthens the Nation's position.

CONSERVATION

Basically, conservation entails wise use—not hoarding. Wise use in the mineral field in turn requires high eventual recovery of material from the ground and of the valuable constituents of such material; recovery at the time needed; fabrication or other preparation for use with minimum waste or loss of the valuable

material; efficient utilization through superior design in fabrication or high energy conversion in combustion; high recovery of coproducts and byproducts or storage of wastes for later treatment; application to purposes of high economic utility; and utilization of substitutes, where available, for other important materials that either are in limited reserve or have singular use characteristics not common to other minerals.

PROBLEM ATTACK—OBJECTIVE ACHIEVEMENT

Before attacking the problems of specific mineral commodities, relevant facts must be assembled and reviewed. The 88 chapters of this volume, each devoted to a mineral commodity or a group of closely related commodities, consist largely of a presentation of facts arranged in a standard pattern. The size, organization, and distribution of the industry are outlined; its technology briefed; byproducts, coproducts, substitutes, synthetics, and secondary products covered; reserves estimated; uses described; strategic and defense considerations reviewed; prices, costs, taxes and tariffs, and their trends presented; and other salient statistics and statistical trends set forth. Finally an outlook section is presented, and current and foreseen problems are identified.

The attacks on mineral problems may be simple and direct, or they make take the form of a broad, scientific assault on the unknown in the expectation that new knowledge will provide keys to the solution of problems both old and new. Thus the avenues of attack on mineral problems range from basic or pure research on the properties of minerals to the testing of specific ores as to their amenability to particular processes. Also of great importance is the distinction between technical feasibility without regard to economic feasibility and commercial or industrial applicability. Laboratory-scale work oriented to technical feasibility is usually classed as research. Beyond that stage comes engineering evaluation. Frequently there also must be investigations in pilot and demonstration plants before the ultimate design of commercial installations. These latter stages along with market analyses and consideration of other economic factors lie in the field of mineral-industry studies.

Research to acquire knowledge is the province of the scientist, whereas the job of applying knowledge to solve industrial problems lies largely with the engineer.

RESEARCH

Research in metallic or nonmetallic minerals, coal, petroleum, or natural gas may be undertaken separately, but all have problems in common and the scope and magnitude of effort in each field should be guided by their interrelationship. Industry, largely because its units are normally specialized as to both commodities and functions, will not or cannot use the comprehensive approach easily available to the Government. Thus Government has a unique role in coordinating and integrating research in the mineral industry.

In bringing mineral resources into man's service, aggressive research—from basic science through applied technology and including economic investigation—must characterize all stages, first in determining where and how best to explore and then on through exploration, development, production, processing, refining, utilization, marketing, and reclamation for reuse.

In nonfuel minerals, research is needed on exploration devices and techniques and on development drilling; physical research is needed on new materials. Equally urgent is the need for effective research in mining technology (mining methods, mechanization, transportation, rock breaking, loading, and integration of operation) and in milling, preparation, and beneficiating technology (crushing and grinding, flotation and gravity concentration, magnetic and electrostatic concentration, pneumatic methods, flowsheet development, and tailings disposal).

Metal extraction embraces smelting (furnace design, temperature control, atmospheric control, and slag and melt composition), hydrometallurgy and chemical processing (leaching, filtering, and electrolytic and chemical precipitation), nodulizing and briquetting, refining, and combinations of these and other techniques under special circumstances. Similar processing is involved in many minerals, particularly those of the nonmetal group. In all extractive metallurgy there is special need for research in making low-grade and refractory ore deposits available for use.

Recovery of scrap and its preparation for reuse are highly important phases of conservation of resources. Research can increase the efficiency of scrap processing.

In mineral-fuel research, more effective utilization of coal may be brought about by developing a larger and cheaper supply through more economical mining methods. Whereas generation of electricity and high-temperature

coking now provide the main markets for coal, perfection of processes under study—some of which have been or are now being used on an industrial scale—may create or expand demand for this abundant mineral as a source of organic chemicals, fertilizers, high calorific value gas, liquid fuels, and oils. Among the processes receiving great attention are direct hydrogenation, low-temperature carbonization, and gasification with subsequent utilization in the methanation reaction or the ammonia, the oxo, or the Fischer-Tropsch synthesis.

In petroleum and natural gas research, there are equal and parallel needs to meet. Improved drilling equipment and techniques will continue to offset costs of deeper drilling and rising ratios of drilling to discovery. Better methods of production (pressure maintenance, water flooding, in situ combustion, use of detergents, and utilization) will make available material now discounted in reserve estimates. Separation, identification, and characterization of the component parts of crude petroleum and natural gas will provide a sound basis for meeting changes in requirements for the end uses of these materials. Research also is the key to commercial utilization of the enormous U.S. oil shale resource.

MINERAL INDUSTRY STUDIES

The ever-changing mineral needs of industry and defense, supplied by sources subject to depletion by exploitation and to replenishment by discovery and development, require that the results of successful scientific and technologic research be applied aggressively and unremittingly to the mineral-supply situation. Wise and efficient use of natural resources depends to a large measure on resource factfinding as carried on in the field by geologists and exploration engineers and on advances in technology of mining and metallurgical extraction.

Increased mineral utilization is fostered by mineral-industry studies that point out commercial opportunities resulting from scientific and technical discoveries affecting minerals and from economic advances in other fields. Consumers and communities have new opportunities in many fields, provided by discovery of ore bodies, proof of sizable reserves, development of new or more efficient extraction methods, and new or improved sources of energy from mineral fuels to convert such ores to useful products.

On the other hand, increasing populations, advancing industrialization, new applications, and other elements of demand will call for a review of latent or partly developed resources as a new or expanded source of supply. New facilities like roads, railroads, canals, electric powerlines, natural gas pipelines, and other such developments may call for a reassessment of local mineral resources and the marketability of their products. Mineral-industry studies concentrate on such problems of supply and demand adjustment on a local, regional, or national basis as appropriate.

BASIC ECONOMIC TRENDS

The mineral industries have much in common with each other and with all other industry. The whole economy shares in such changes as growing demand based on population increase, rising gross national product, deflation and inflation of the currency, and several other shifting factors. The accompanying tables 1 to 6 and figures 1 to 6 present such data either directly or as indexes and in some instances include projections. The trends set forth have been basic to much of the commodity forecasting to be found in the "Outlook" sections of the commodity chapters.

TABLE 1.—*Population and total labor force of the United States* [1]

ALUMINA AND BAUXITE

By Lloyd R. Williams [1]

ALUMINA (Al_2O_3), the raw material used for the production of aluminum, occurs widely and comprises about 15 percent of the earth's surface. However, only material identified as bauxite, in which the alumina has been concentrated by weathering processes, qualifies commercially as a source of alumina under present economic and technical conditions.

World consumption of alumina in 1963 was estimated at 13 million short tons; about 50 percent was consumed in North America and 41 percent in Europe. The consumption of alumina in the United States in 1963 was about 5 million tons and by 1980 annual consumption may be 18 million tons.

World bauxite production in 1963 was estimated at 29.8 million tons of which 51 percent was produced in the Western Hemisphere. About 94 percent of the bauxite consumed in the United States is used in alumina production and the remainder in making abrasive, chemical, and refractory products. Bauxite consumption in the United States was 11.3 million long dry tons in 1963 and by 1980 consumption may be 40 million tons.

Although the United States produces essentially all of its alumina requirements and is the world's largest consumer of bauxite, less than 15 percent of its bauxite requirement is produced domestically.

The domestic bauxite reserve which is mainly in Arkansas is estimated at 50 million tons averaging about 52 percent Al_2O_3. The reserve is too small to permit production to be expanded significantly. The total world reserve of bauxite at the end of 1963 was estimated at 5.8 billion tons with the largest deposits in Australia, Guinea, Jamaica, Hungary, Yugoslavia, Surinam, and Ghana.

As a result of improvements in technology it has been possible to reduce the grade of ore used in alumina plants. In 1930 ore used in the United States averaged 60 percent alumina, but by 1963 the average was less than 50 percent.

The average grade of ore treated probably will continue to decrease gradually, and successful application of processes now being tested could result in use of material containing less than 35 percent alumina.

Bauxite, an ore containing hydrated aluminum oxide minerals such as gibbsite, boehmite, or diaspore, is formed by weathering processes acting on alumina-bearing rocks. The largest deposits occur in tropical or subtropical climates and are at or near the surface. Most bauxite is mined by open-pit methods, but bauxite also is recovered by underground mining methods in the United States and in Europe.

Assurance of an adequate and dependable long-range supply of alumina requires discovery of new sources and the solution of numerous mining and metallurgical problems. A challenging problem is the development of a commercial process for producing alumina from domestic low-grade materials. Problems of the Bayer process include the need to improve its efficiency and development of methods for utilizing tailings. There is insufficient information on quantity, grade, and type of potential alumina resources, and exploration is handicapped by lack of a rapid method of analyzing for alumina. Mechanical beneficiation of low-grade bauxites is hampered by the high loss of alumina in removing iron and silica.

BACKGROUND

SIZE, ORGANIZATION, AND GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

World bauxite production in 1963 was estimated at 29.8 million tons of which 51 percent was produced in the Western Hemisphere. Jamaica, Surinam, and British Guiana continue as the major producers in the Western Hemisphere. Although bauxite mining started as late as 1952 in Jamaica, the country became the major world producer in 1957 and continues to

[1] Commodity specialist.

maintain that position. Nearly half of the bauxite consumed in the United States in 1963 was produced in Jamaica.

World alumina consumption in 1963 was estimated at about 13 million tons, of which 38 percent was consumed in the United States, 41 percent in Europe, 12 percent in Canada, and 4 percent in Japan. In 1963 most of the alumina plants were in or near the consuming country. However, in recent years the tendency to build alumina plants near the source of the raw material to reduce transportation costs, has been evident. Aluminum producing companies operate most of the bauxite mines and own the alumina production facilities.

The actual and planned capacity and location of the U.S. alumina plants, their sources of bauxite, and the aluminum plants, that consume most of the alumina production are shown in figure 1.

Approximately 94 percent of the alumina shipments in 1963 went to the aluminum industry; the remainder was shipped to abrasive, refractory, chemical, or other plants.

Eight alumina plants used about 94 percent of the bauxite consumed in 1963. The remaining 6 percent was consumed by about 80 companies in about 200 plants including helium-producing plants and municipal waterworks. Three of the four alumina producers are vertically integrated from mining through production of semifabricated aluminium. Two of the integrated producers, Aluminum Company of America and Reynolds Metals Co. use both domestic and foreign bauxite. The third, Kaiser Aluminum & Chemical Corp., uses only foreign bauxite from its own mines. The fourth producer, Ormet Corp., uses bauxite purchased from a foreign source. In 1963 six independent companies produced bauxite in the United States on a small scale mainly for specialty uses. In Arkansas Campbell Bauxite Co. and Stauffer Chemical Co. produced dried bauxite. Activated bauxite was produced by these same two companies and Porocel Corp. Calcined bauxite was produced by American Cyanamid Co. In Alabama crude ore was shipped by Wilson-Snead Mining Co. (formerly D. M. Wilson Bauxite Co.). Dried bauxite was produced by R. E. Wilson Mining Co. and calcined bauxite was produced by Harbison-Walker Refractories Co. In Georgia, American Cyanamid Co. shipped crude ore and also produced dried bauxite. About 1 million tons of bauxite per year is consumed directly without passing through an intermediate alumina production stage. All of the ore from Alabama and Georgia is consumed directly together with some from Arkansas and a minor part of the imports.

Bauxite exports represented about 2 percent of the new supply of which 85 percent was imported.

DEFINITION OF TERMS, GRADES, AND SPECIFICATIONS

Bauxite is a rock composed principally of the aluminum oxide minerals, gibbsite, boehmite, and diaspore. *Gibbsite* is a trihydrate ($Al_2O_3 \cdot 3H_2O$). *Boehmite* and *diaspore* are monohydrates ($Al_2O_3 \cdot H_2O$). Major impurities in the bauxite ores are iron oxides, aluminum silicates, and titanium oxides. Types of bauxite ores are generally identified as Jamaican, Surinam, and European. The *Jamaican type* is a mixture of both trihydrate and monohydrate minerals and containing about 50 percent Al_2O_3, 1 to 2 percent silica, and 20 to 30 percent iron oxide. The *Surinam type* is mainly the trihydrate gibbsite usually containing 50 percent or more Al_2O_3, 2 to 15 percent silica, and 5 to 15 percent iron oxide. The *European type* contains the monohydrates, boehmite and diaspore, and is about 55 percent alumina, 4 percent silica, and 10 to 20 percent iron oxide.

Crude bauxite is bauxite as mined containing from 5 to 25 percent free moisture.

Activated bauxite is used as an absorbant to refine sugar syrups and liquors, dehydrate and filter petroleum products, and act as a drying agent in industrial processes. It is processed by crushing and heating selected bauxite at 250° to 350° F to remove free water. After further crushing and screening it is thermally activated, the temperatures differ depending on the various uses of the product. The activated bauxite is cooled to 300° F and screened and deironed. It can be regenerated repeatedly for a number of cycles by controlled heating.

Dried bauxite is prepared by heating crude bauxite in a drying kiln at about 1,100° F for 15 to 40 minutes to reduce the free moisture to less than 1 percent. Uncontrolled heating may cause calcining and reduce the solubility of the alumina hydrate in the Bayer process.

Calcined bauxite for the abrasive and refractory industries is processed by heating in kilns at 1,700° to 2,900° F depending on use for about 1 to 1.5 hours to reduce total volatile matter including the chemically combined water in the ore to less than 1 percent. About 2 tons of crude ore produces 1 ton of calcined bauxite.

Bauxite specifications vary with plant and ultimate use. National stockpile specifications for all grades except chemical have been established (*3*).[2]

[2] Italicized numbers in parentheses refer to items in the list of references at the end of this chapter.

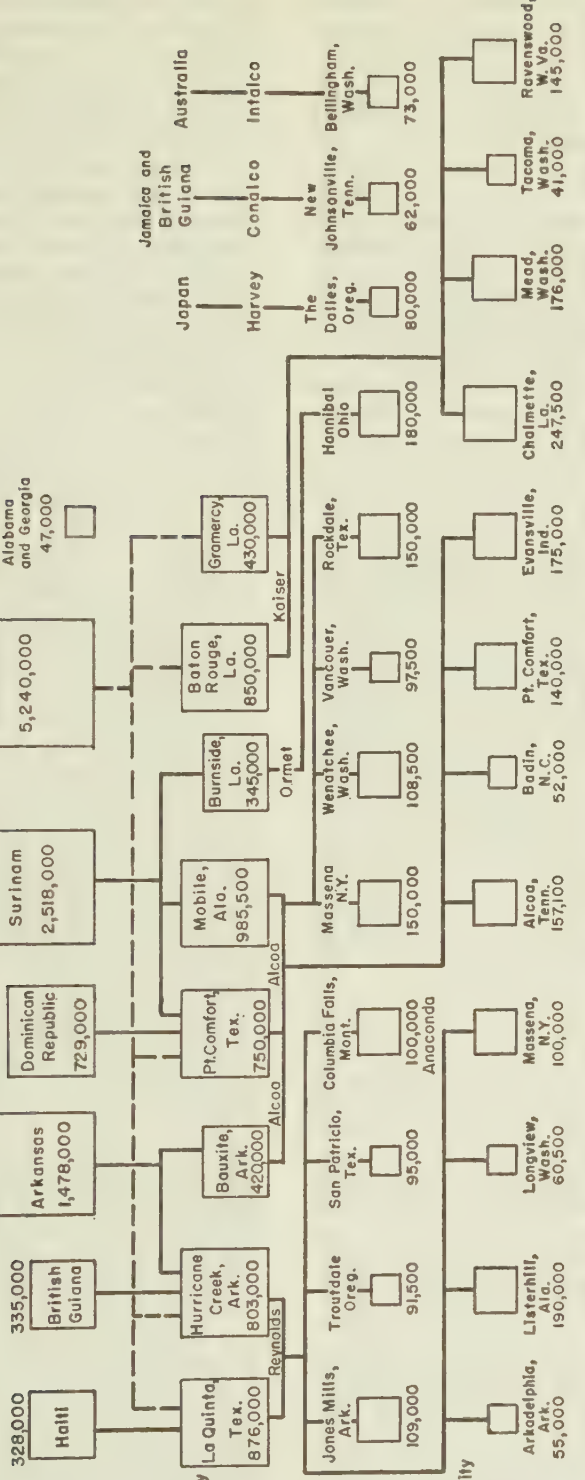

FIGURE 1.—Bauxite Supply and Alumina- and Aluminum-Plant Capacities in the United States in 1963 (Includes Plants Under Construction).

Table 1 gives the chemical analyses of bauxite used by the metallurgical, abrasive, chemical, and refractory industries.

TABLE 1.—*Chemical analysis of typical bauxites, by grade* [1]

[Percent]

Grade	Al_2O_3	SiO_2	Fe_2O_3	TiO_2
Metallurgical	50–55	0–15	5–30	
Abrasive	Min. 55	Max. 5	Max. 6	Min. 2.5
Chemical	Min. 55–58	Max. 5–12 [2]	Max. 2	
Refractory	Min. 59–61	Max. 1.5–5.5	Max. 2	Max. 2.5

[1] Most of the remainder represents water of crystallization.
[2] A major portion of the bauxite used by the U.S. chemical industry exceeds 15 percent.

Red mud the residue that results after alumina is extracted from bauxite by the Bayer process, consists largely of a complex sodium aluminum silicate and iron oxides. In the combination process the red mud is the feed to a subsequent lime-soda sinter step. The residue from the combination process is called *brown mud* or *sinter mud* and contains calcium silicates and iron oxides but little sodium aluminum silicate.

Alumina is aluminum oxide Al_2O_3, the calcined product of Bayer or combination processes. Corundum, emery, ruby, and sapphire are natural mineral forms. In the commercial form it is a fine white powder containing about 0.5 percent impurities. A typical analysis of alumina used in the production of aluminum follows:

	Percent
Chemical composition:	
Silica (SiO_2)	0.02
Iron oxide (Fe_2O_3)	.02
Titanium dioxide (TiO_2)	.003
Phosphorus pentoxide (P_2O_5)	Nil
Potash (K_2O)	Nil
Sulfur trioxide (SO_3)	Nil
Soda (Na_2O)	.45
Calcium oxide (CaO)	.02
Lead (Pb)	Nil
Alumina (Al_2O_3)	Bal.
Ignition loss and water absorption:	
Loss on ignition (1,000° C)	2.67
Water absorption (bone dry-basis)	3.16
Screen analysis (Tyler mesh):	
+48	Nil
−48+100	.5
−100+200	53.5
−200	46.0
−325 (wet on original sample)	12.0

Activated alumina is a highly porous and granular form of aluminum oxide having preferential adsorptive capacity for moisture from gases, vapors, and some liquids. When saturated it can be reactivated by the controlled application of heat within the range of 350° to 600° F to drive off the moisture. It is used as a drying agent, catalyst, or catalyst carrier.

Calcined alumina is a high-purity alpha-alumina produced by heating at 2,000° to 2,300° F hydrated alumina ($Al_2O_3 \cdot 3H_2O$) precipitated from soduim aluminate liquor in refining of bauxite ores by the Bayer process. Production of aluminum is the principal use of calcined alumina. Various grades of calcined alumina are produced under carefully controlled conditions for the manufacture of fused alumina abrasives and high-temperature refractories. High-grade ceramic shapes are made from alumina calcined at 2,700° to 2,900° F with a high melting point of 3,700° F and a hardness of 9 on Mohs' scale.

Tabular alumina, also Al_2O_3 is prepared by heating $Al_2O_3 \cdot 3H_2O$ to slightly below the fusion point of alumina (3,700° F). It is used in refractories, in insulators, and as a filter in plastics.

TECHNOLOGY

Geology and Exploration

Bauxite is formed by the weathering of alumina-bearing materials such as feldspars or clays. Ideal conditions, most likely to occur in wet tropical or subtropical climates, are nearly continual rainfall, constant warm temperatures, and relatively good drainage over a long period of time (*1*). The degree of acidity or alkalinity of the weathering solutions determines whether hydrated aluminum oxides or hydrated aluminum silicates form.

The Arkansas bauxite deposits were formed by weathering of nepheline syenite intrusions of Tertiary age during the period between the formation of the Midway marine clays and the deposition of the Saline formation of the Wilcox group of continental sediments. Some later transported deposits were formed in the unconsolidated clays and sands near the syenite stocks. The bauxite deposits in the Southeastern States were found within flat-lying kaolin bodies overlain by sand and clays of early Tertiary age.

In Jamaica large lateritic deposits were formed on karsted Tertiary limestones by reaction of oxygenated water and carbonic acid with sodium and calcium aluminum silicates to produce gibbsitic bauxite. The deposits are soft, uniformly porous and dark-red or yellow to white and are found in solution pockets, sinkholes, and troughs on the uneven eroded surface of Oligocene and lower Miocene calcareous limestones (*12*).

In Europe the formation of bauxite extended from Triassic through Cretaceous and Tertiary time. The boehmitic and diasporic deposits in France and Greece are residuals on top of lower Cretaceous limestones. Bauxite deposits in British Guiana and Surinam lie on top of Precambrian clays and are covered by tertiary sands and clays. They were formed by leaching actions on kaolin in material transported to low-

land areas from upland weathered metamorphic and igneous rocks.

Western African bauxite deposits usually are associated with the weathering of schistose rocks, and Indian and Australian bauxites are associated with basalts.

Many of the bauxite deposits are covered by little, if any, overburden. Prospecting is done along the unconformable surfaces on which the weathering interval was suitable for the formation of bauxite. There is no rapid method of chemical analysis for alumina, but differential thermal methods have been developed for quick approximations of the kaolinite and gibbsite content of samples.

Since bauxite forms by weathering, deposits usually are nearly horizontal and lie close to the surface. Initial drilling is done at 400- to 4,000-foot intervals, depending on the depth and continuity of the deposit.

Mining

Open-pit mining accounts for 88 percent of the bauxite produced in the United States. In Arkansas, stripping is done by draglines, shovels, and Carryalls. Stripping ratios of as much as 10 feet of overburden to 1 foot of ore are minable and a ratio of 15 to 1 is considered feasible. Several pits in Arkansas have been mined to depths of more than 100 feet, and about 200 feet is estimated to be the present economic limit for large ore bodies. The pits stand well for unconsolidated rocks, but slumping does occur. Deeper flat-lying ore is recovered at Reynolds Mining Co. Hurricane Creek mine in Arkansas by an underground method of room-and-pillar mining along a retreating cave line. Development is advanced, on a diamond-shaped pattern to the ore limits or caved area and a retreating cave line is induced by systematic pillar recovery closely following room excavation (*34*).

All efforts are made not to leave any unmined ore inside the cave line to avoid excessive pressure on unmined blocks of ore. The caved ground is kept from diluting the broken ore by timbered retaining walls. A cap of about 2 feet of bauxite is left to help support the overlying weak unconsolidated clays and sandstones.

In Jamaica the bauxite deposits lie close to the surface and the overburden of vegetation and topsoil is easily stripped (*13*). The ore is broken by drilling and blasting or by the use of rippers. Shovels, draglines and scrappers are used to load the ore. Haulage is by truck, railroad or aerial tram line to the dryers or alumina plants near port facilities. In Surinam as much as 80 feet is stripped by draglines, hydraulic giants, or dredges. The same methods are used in British Guiana to remove the overburden. The ore is broken by blasting and loaded into ore cars with power shovels (*23*).

Underground mining accounts for more than 80 percent of French bauxite production and is widely used in other parts of Europe including the U.S.S.R. European deposits frequently are in steeply folded limestone beds, and the ore-shoot pattern is typical of sinkhole deposition. Room-and-pillar or shrinkage stoping is used depending on size, dip of the ore body, and condition of the ground.

Restoration of mined-out open-pit areas to usefulness is required in Jamaica and is becoming increasingly important in other areas. Subsidence where bauxite was extracted underground is of minor importance today but may become more serious in the future.

Beneficiation

Bauxite is often washed to remove silica or clay minerals. The high-iron ores of Surinam are concentrated by jigging or heavy-medium separation.

In submarginal bauxites the iron oxides, clay minerals, and part of the titanium minerals are often so finely dispersed through the ore that physical methods have not produced successful separations.

During World War II a pilot plant was operated by the Bureau of Mines at Bauxite, Ark., to test various ore-dressing procedures, including gravity, flotation, and magnetic methods (*30*). Beneficiation by magnetic techniques to eliminate iron is practiced on a limited scale on bauxite for nonmetallurgical uses (*6*).

Processing

Although research on the extraction of alumina has continued for many years, virtually all of the commercially produced alumina is obtained by a process patented by Karl Bayer in 1888 (German Patent 43,977) for use on bauxite. A number of modifications and improvements have been made in the process to adapt it to various types of bauxite. The process involves a caustic leach at elevated temperature and pressure, followed by separation of the resulting sodium aluminate solution, and selective precipitation of the alumina. There are two principal variations of the Bayer process: (1) The European Bayer, in which the approximate conditions of leaching are a pressure of 210 pounds per square inch, a temperature of 390° F, a caustic concentration of 400 grams per liter, and a digestion time of 2 to 8 hours to effect solution of the monohydrate mineral boehmite and (2) the American Bayer, in which a pressure of about 60 pound per square inch, a temperature of about 290° F, a caustic concentration of 170

grams per liter, and a digestion time of one-half to 1 hour are used to dissolve the trihydrate mineral gibbsite (*1*, *25*). The American process is used for treating trihydrate bauxites, because it requires less evaporation and lower temperatures and is more adaptable to continuous digestion.

In both processes the pregnant solution is separated from the red mud tailings by countercurrent decantation and filtration. The liquor is cooled until it becomes supersaturated, then seeded with crystals of aluminum trihydrate. About one-half of the alumina in solution is precipitated in a 36- to 96-hour period. The precipitate is then filtered, washed, and calcined at 2,000° F to obtain the final product. Caustic soda is regenerated in the precipitation step and, together with the unprecipitated alumina, is recycled to the digesters. For some nonmetal uses the alumina is left in the trihydrate form or is only partly calcined.

The finely divided residue resulting from leaching contains Fe_2O_3, TiO_2, and a complex sodium aluminum silicate compound. This compound represents a loss of soda and alumina, and the quantity discarded in the residue is related to the silica content of the bauxite. Approximately 1.1 units of alumina and 1.2 units of soda are lost for each unit of silica in the ore. Bauxite must contain less than 8 percent silica for economic treatment by the Bayer process.

Approximately 4 long dry tons of bauxite is required to produce 2 short tons of alumina, which will yield upon electrolysis slightly more than 1 short ton of aluminum. The materials other than bauxite required in the Bayer process are soda ash; lime for causticizing the soda ash; and fuel oil, gas, or coal.

Crude bauxite from the mines usually is crushed to about 2-inch size in hammermills, gyratories, or jaw crushers. Free moisture, but not the water of crystallization, is removed from the ores by drying when they are to be transported appreciable distances. Bauxite from Surinam and British Guiana is dried to less than 3 percent free moisture. Bauxite from Jamaica and Haiti, after drying, may still contain as much as 15 percent free moisture to prevent dusting when the ore is transported. Further treatment depends upon the end use. Ores for refractory uses are calcined in rotary kilns at 2,500° to 2,900° F and for abrasive uses at 1,700° to 2,400° F to remove water of crystallization.

Bauxite with more than 8 percent silica is treated by the combination process (*3*), which first became commercial as a result of the reduced supply of imported high-grade bauxite during World War II. In this process, bauxite containing 12 to 15 percent silica is first subjected to a Bayer leach. The resulting red mud, which contains the complex sodium aluminum silicate compound, is sintered with limestone and soda ash, then leached with water to recover alumina and soda. The brown mud residue has a composition, on a dry basis, somewhat similar to that of portland cement.

The additional cost required in capital investment, raw materials, and processing by the combination method is partly offset by higher recoveries of alumina and soda and partly by lower mining costs. A major advantage of the combination process is the decreased need for selective mining, as high-silica bauxite, previously regarded as unsuitable for alumina production, can be used. The upper limit of silica for use in this process is now about 15 percent; however, in practice, bauxite containing as high as 25 percent silica is mined and blended with low-silica ore in proportions that will give a feed material of approximately 12 to 13 percent silica. The combination process is used in the two plants in Arkansas and in plants in the U.S.S.R.

In 1952 the American Bayer process was modified to treat the high-iron, low-silica bauxite of Jamaica. The major modifications resulted from difficulties in filtration of the red mud slurry and from the small amount of boehmite in the ore.

In the U.S.S.R., alumina is extracted from nephelite flotation concentrate containing about 30 percent alumina, obtained as a byproduct of apatite from deposits in the Kola Peninsula. The process used is a variation of the lime-soda sinter method, but no soda is added as it is already present in the feed.

In Norway alumina is extracted commercially from high-iron bauxites by the Pedersen smelting process. In this process, bauxite, limestone, coke and iron ore are smelted in an electric furnace to produce pig iron and a calcium aluminate slag containing 30 to 50 percent alumina. The slag is leached with sodium carbonate solution, and the alumina trihydrate is precipitated by carbon dioxide. During World War II the process was also used at a Swedish plant to treat andalusite.

USES

More than 90 percent of the bauxite consumed in the United States is used to make alumina. Less than 10 percent is applied to other uses such as abrasive, refractory, and chemical including aluminum sulfate and other aluminous chemicals used in water and sewage treatment, dyeing, tanning leather, and sizing paper. Bauxite is also used in the production of high alumina cement, in low density insulating materials, as an adsorbent or catalyst by the oil industry, and

as a flux in making steel and ferroalloys. Fused bauxite is used in bonded or coated abrasives or as abrasive grain.

About 94 percent of the alumina production is consumed by the aluminum industry. Alumina also is used for abrasive, refractory, or chemical applications in which a high degree of purity is desirable. Its minor uses include production of the nose cones of missiles, artificial sapphires, and thread guides for textile plants.

BYPRODUCTS

Most bauxites contain small quantities of gallium and vanadium, which dissolve in the Bayer process liquors. Gallium is recovered in the United States by one company, and vanadium is recovered in a French operation. In Norway, iron is produced as a byproduct of the Pedersen process. In the U.S.S.R., potash, soda, and cement are produced as byproducts in recovering alumina from nepheline syenite.

RESERVES

The world bauxite reserve of about 5.7 billion tons and potential resource of about 8.7 tons shown in table 2 were estimated in 1963 by the U.S. Geological Survey. In addition to the countries shown, bauxite also was reported to occur in Poland, Mali and Upper Volta, Portuguese Guinea, Republic of the Congo, Tanzania, North Viet-Nam, and Pakistan (*24*).

Estimates of world bauxite reserves increased 79 percent or an average of about 12 percent per year since 1958 and potential resources increased 46 percent or an average of about 8 percent per year. Australia and Guinea with 57 percent of the world bauxite reserve accounted for most of the increase in reserves. Most of the increase in potential resources was contributed by Australia and Cameroons.

In 1963 the U.S. bauxite reserves totaled 50 million tons averaging about 52 percent Al_2O_3 and 10 percent SiO_2. Of this, 98 percent is in Arkansas and 2 percent in Georgia and Alabama.

The potential bauxite resources shown in table 2 are deposits too low in grade, too deep, too thin, or too remote for profitable recovery under present conditions. The potential bauxite resource, associated with the bauxite reserve in Arkansas, is estimated at 65 million tons. About 25 million tons of low-grade gibbsitic bauxite containing substantial amounts of kaolinite are reported in the Southeastern States. Lower grade ferruginous bauxite deposits in Washington and Oregon formed by weathering of basalt are estimated at 85 million tons. The potential resource in Hawaii is 125 million tons of low-grade bauxite in soils and saprolite weathered from basalt (*8*).

Vast amounts of inorganic materials composed of anorthosite, kyanite, nepheline syenite, alunite, audalusite, and other clays, shales, and slates containing less than 32 percent Al_2O_3 extend over the surface of the earth. These are not included in table 2 but may eventually become a potential resource.

TABLE 2.—*Estimate of world bauxite reserves and potential resources, December 1963 (24)*[1]

[Million tons]

Country	Reserves[2]	Potential
North America:

Fiji Islands, New Zealand, and Palau Islands	5	20
Total	2,065	1,210
Grand total	5,760	8,740

[1] Most of the estimates are in metric or long tons, dry basis; however some estimates did not designate size of ton, wet or dry.
[2] Mostly measured and indicated reserves that could be used under economic and technological conditions existing in 1963.

SOURCES OF STATISTICAL INFORMATION

Statistical information on stocks and production of alumina and shipments of alumina classified by recipient industry are collected annually by the Bureau of Mines. The Bureau

also collects data on the consumption of alumina by the aluminum industry.

Statistical information on domestic bauxite is collected and published periodically by the Bureau of Mines and the Bureau of the Census. Other sources of information include special studies presented in the technical press, reports of aluminum producers and investment companies, and reports by other agencies such as the Federal or State Geological Surveys. The Bureau of Mines publishes quarterly reports and a comprehensive annual report.

Information on foreign bauxite consumption is almost wholly lacking, and data on alumina production and trade in foreign countries are incomplete.

PRODUCTION, CONSUMPTION, AND TRADE

Table 3 shows domestic alumina production and shipments to consuming industries by producers. From 1959 through 1963 shipments to the aluminum industry represented 94 percent of the total shipments. In 1963 exports of alumina were about 10 percent more than imports. Each represented about 4 percent of the total alumina consumed in the United States.

U.S. production, imports, and consumption of bauxite are shown in tables 4 and 5 and world production in table 6.

Exports of bauxite, 1959–63, on a dried-bauxite equivalent basis, ranged from 30,000 to 401,000 tons, averaging about 205,000 tons per year. Of the total exports during this 5-year period 66 percent was exported to Canada and part was returned to the United States as abrasives.

The duties on crude bauxite, calcined bauxite, and alumina imported for making aluminum were suspended until July 7, 1966. Duties on aluminum hydroxide and alumina not used for aluminum production were 0.25 cent per pound.

TABLE 3.—*Production and shipments of alumina in the United States, calcined equivalent*

[Thousand short tons]

Year	Production	Shipments

STRATEGIC CONSIDERATIONS

Previous to 1958 domestic production of alumina met practically all United States requirements. However, in 1958 a U.S. aluminum producer with a capacity of about 54,000 tons, began importing alumina from Japan.

Table 4 shows United States self-sufficiency in bauxite for recent years. The domestic reserve of bauxite is sufficient to maintain an annual production of approximately 1.5 million tons for several decades; the increasing demand must be supplied by imports until production of alumina from domestic low-grade alumina-bearing raw materials, becomes competitive with production from imported bauxite.

Government-owned stocks of bauxite held by Office of Metals Reserve were declared surplus on June 30, 1946, and transferred to the Bureau of Federal Supply and were maintained as the national strategic stockpile. Government inventories on June 30, 1964 are shown in table 7. In addition stocks of refractory grade, calcined bauxite were 300,000 long tons and crude fused and abrasive grain alumina were 400,000 short dry tons.

GOVERNMENT PROGRAMS

During World War II alumina plants were built by the Government to meet the requirements of the aluminum industry. Bauxite reserves in the United States were more than doubled as a result of an extensive exploration program undertaken by the Federal Government and industry. Other Government programs assisted the sharp expansion in domestic bauxite production from less than 500,000 tons in 1940 to the record high of about 6 million tons (dry equivalent) in 1943 and dropping to less than 1 million tons in 1945. Since then production has averaged about 1.5 million tons per year.

During Korean hostilities mining operations in Jamaica and Surinam were increased with U.S. Government assistance. The construction of domestic aluminum plants was encouraged through issuance of accelerated tax amortization certificates and guaranteed market contracts for aluminum.

With the expanding production of aluminum in the United States and the limited reserves of domestic bauxite the Bureau of Mines inaugurated a program to ascertain the technology required to produce alumina from alumina-bearing raw materials. A series of reports have been published on process evaluations to determine the relative processing costs of producing metallurgical-grade alumina from low-grade aluminous materials. The reports include recommendations for additional research and development to improve the processes and to lower their costs (*26–29*).

TABLE 7.—*Bauxite in Government inventories*

[Thousand long dry tons]

Metal grade	National (strategic) stockpile	DPA stocks	CCC stocks	Supplemental stockpile	Total
Jamaica type	880	1,370	805	5,781	8,836
Surinam type	4,963			2,927	7,890

PRICES AND COSTS

Most bauxite is either consumed by the producing companies and their affiliates or purchased under long-term contracts without an open-market price.

Prices per long ton quoted in E&MJ Metal and Mineral Markets for imported bauxite at yearend in 1962 and 1963 were as follows:

	British Guiana f.o.b. port, Dec. 31, 1962	*Atlantic ports f.o.b. cars, Dec. 30, 1963*
Calcined, crushed (abrasive grade)	[1] $21.45	[2] $25.50–$27.50
Refractory grade	27.85	[3] 34.75
Dried bauxite, crushed, chemical grade (60 percent Al_2O_3, 6 percent silica, 1¼ percent iron)	[4] 7.25	13.95

[1] 86 percent minimum Al_2O_3.
[2] 87 percent minimum Al_2O_3.
[3] 87 percent minimum Al_2O_3.
[4] F.o.b. vessels.

The value of shipments of alumina and bauxite as reported by producers is shown in table 8.

TABLE 8.—*Average values of bauxite and calcined alumina*

Year	Bauxite, per long dry ton		Calcined alumina per short ton [3]
	Domestic [1]	Imported [2]	
1954–58 (average)	8.69	8.01	63.56
1959	10.43	9.03	66.80
1960	10.56	8.93	69.80
1961	11.35	9.65	68.80
1962	11.40	11.53	67.20
1963	11.30	12.44	65.20

[1] Average value of mine production.
[2] At port of shipment, as reported to the Bureau of the Census.
[3] Average value of shipments.

TAXES

A State severance tax of $0.10 per short wet ton is levied on bauxite mined in Arkansas. Domestic producers are granted a depletion allowance of 23 percent on income from domestic production and 15 percent on income from foreign production.

The total income from taxes and royalties on exported bauxite and alumina received by the Jamaican Government in 1962 was about $20 million. Exports in 1962 were 6 million tons of bauxite valued at $44 million and 630,000 tons of alumina valued at $40 million or a total bauxite equivalent of 7.4 million tons (dry weight).

Royalties in Surinam are 5 percent or less of the gross value of the product. In 1962 the Surinam Government reported receipts of $5.3 million as royalties and taxes on 3.3 million tons of exported bauxite.

TRANSPORTATION

About 85 percent of the bauxite consumed in the United States is transported from Caribbean islands and the north coast of South America. Ore mined in Surinam and British Guiana is transported from the mines near a river by barge or river vessel to processing plants near the coast. The bauxite is either dried or processed into alumina before loading onto ocean-going ships. Ships leaving British Guiana are lightly loaded to clear an offshore reef. Bauxite-loaded ships are topped at Chaquaramas, Trinidad, and those loaded with alumina are topped at Esquivel, Jamaica.

In Jamaica the bauxite is trucked to railroad loading ramps and transported by gondola cars to drying kilns or alumina plants located at seaports. Some of the bauxite processed at one of the two alumina plants is transported from the mine by aerial tram. The dried bauxite and alumina are loaded onto ore boats of up to 37,600-ton capacity for shipment.

The bauxite and alumina assigned for consumption in the United States is transported to Gulf ports where most of the bauxite is processed into alumina. Nearly all of the domestically processed alumina and the imported alumina and some of the imported bauxite is shipped by railroad cars, barges, trucks and ocean going ships to aluminum plants and other alumina-consuming industries.

Some alumina is transported by ship from Japan to the west coast. Alumina produced in Jamaica and the gulf coast area of the United States is transported by ship through the Panama Canal to aluminum producers in the Northwestern United States and Kitimat, British Columbia.

RESEARCH

During World War II an extensive research program aimed at developing methods for recovering alumina from low-grade ores was undertaken by the Bureau of Mines. Methods for upgrading low-grade bauxites (those with high-silica and/or high-iron content) were investigated. Acid and alkaline processes for extracting alumina were tested and the most promising methods investigated on a pilot-plant scale. During this period other Government and private organizations conducted research on similar processes.

Recent Bureau of Mines research included studies of recovery of alumina from anorthosite by the lime-soda-sinter process (*19*, *20*, *29*, *31*). Studies on properties of aluminum nitride and preparation of aluminum fluoride were investigated (*2*, *18*, *21*).

The Bureau also conducted cost evaluations for the production of metallurgical-grade alumina from low-grade aluminous materials using sulfuric acid, hydrochloric acid, and potassium alum processes (*26–29*). Metallurgical investigations were conducted for recovery of alumina from ferruginous bauxites (*4*, *17*).

All eight companies producing aluminum have laboratories in which research is in progress on improving present processes for recovering alumina from noncommercial materials. The Anaconda Company continued to operate a 5-ton-per-day pilotplant at Anaconda, Mont., for the production of alumina from high-alumina clay using hydrochloric acid. During part of 1962–63, the North American Coal Corp. produced a high-grade aluminum sulfate from coal shale at Powhatan, Ohio. In West Germany a vacuum crystallization technique with sulfuric acid was used to separate aluminum sulfate from iron. Pure alumina was produced experimentally by hydrolysis and alkaline treatment of aluminum sulfide slag.

Hydrolysis was also used to form a basic alumium sulfate (*32*).

In addition, studies at some laboratories were directed toward expanding the use of alumina by refractory, abrasive, petroleum, and other industries.

OUTLOOK

Based on past records and the normal patterns of bauxite use, U.S. consumption is expected to continue to increase between 7 and 8 percent per year during the next 10 to 20 years, and more than 90 percent will be used in the preparation of aluminum metal. At this rate bauxite consumption in the United States would reach about 19 million tons per year by 1970 and 40 million tons by 1980. However, if the tendency to construct alumina plants closer to the sources of bauxite, which has been evident in recent years continues, demand in the United States will not reach this high level. An equivalent quantity of Al_2O_3 probably will still be required.

Domestic production of bauxite is expected to remain at the present rate of about 1.5 million tons per year for the next decade. Increased bauxite requirements will be met by imports. Foreign sources supplied 86 percent of the bauxite consumed in the United States in 1963 and by 1970 they are expected to supply 92 percent.

U.S. imports from Surinam will probably remain relatively constant at about 3 million tons per year. Jamaica, which supplies about half of the bauxite used in the United States, is expanding production and should supply most of the additional bauxite needed.

Bauxite containing in excess of 40 percent alumina will remain the primary raw material source of alumina for the immediate future and the Bayer process is likely to continue to be the principal method for the extraction of alumina from bauxite. By the 1980's it is possible that the industry will begin to process low-grade domestic bauxites, clays, or other materials such as alunite, anorthosite, and leucite containing as little as 30 percent alumina as raw materials for aluminum production.

Total requirements for commercial-grade metallurgical bauxite will be approximately 4 times by weight the quantity of primary metal produced. A decrease in this ratio may take place if processes are developed to reduce aluminum metal directly from the ore, thereby eliminating the intermediate alumina stage.

Alumina used in refractory, abrasive, and chemical applications should continue to use slightly less than 10 percent of the total alumina consumed in the United States. Inherent desirable mechanical and electrical characteristics of alumina should lead to new and expanded uses in missiles and complex electronic systems.

The world production rate for bauxite should parallel that for U.S. consumption. Using about the same growth rate world production of bauxite would reach 50 million tons per year by 1970 and 100 million by 1980.

PROBLEMS

One of the most serious problems confronting the domestic alumina producers is that of acquiring adequate and dependable alternate sources of alumina-bearing materials for the continued use of an expanding industry and freeing the industry from uncertain foreign suppliers. This problem is further enlarged by the foreign governments which plan to improve their economy by processing indigenous minerals to a more advanced state. Thus, in order to secure mineral rights the investing company often must also build an alumina plant, a smelter, and special facilities including electric powerplants within the country.

The domestic bauxite mining industry is faced with the problem of high cost of mining small and underground deposits. Another problem is lack of a rapid method of analysis for alumina to help plan direction of mining and to better control selective mining to obtain a more uniform product and use more low-grade ores. Large-scale open-pit operations are confronted with growing demands for surface restoration. Improvements in transportation are needed to lower the costs of shipping ore and alumina.

Detailed information on the location, extent, grade, and nature of potential resources of aluminum is needed in formulating long-range plans for commercial development of such resources. In addition more research is needed to develop suitable processes for producing alumina from domestic low-grade aluminous materials. Technical problems include the elimination of iron and silica, prevention of gelation of alkaline slurries, lack of stability of alkaline alumina solutions, the need for low-cost acid-resistant construction materials, and the lack of precise knowledge of chemical reactions involved.

Problems in improving the Bayer and combination processes include process inefficiencies related to preparation of ore and digestion conditions, removal of soluble impurities and solids, decomposition of sodium aluminate solutions, calcination of aluminum hydrate, scale-forming tendencies of the liquor in the thickeners, and utilization or disposal of increasing quantities of red mud tailings from plant operations.

ALUMINUM[1]

By John W. Stamper[2]

GROWTH of the primary aluminum industry in the United States has been so rapid that the quantity produced annually now exceeds that of any other nonferrous metal. Since 1955 aluminum production in the United States has exceeded 1.5 million tons annually. Aluminum is of great importance in the aircraft industry, and efficient, competitive operation of many other industries requires a continued supply of the light metal.

The basic process for producing aluminum, developed independently by Hall and Héroult nearly 75 years ago, is by electrolysis of high-purity aluminum oxide in a bath of molten cryolite. Research in reduction cell design and development of larger cells has led to economies in power and manpower requirements. There has been much research on other processes for recovery of the metal, but none has proved more economical.

Except for a few years immediately before World War II the United States has been the world's leading producer of aluminum and accounted for 38 percent of world output in 1963. The output of the U.S.S.R., the second largest producer, represented an additional 17 percent of the total. For the past 10 years U.S. imports have accounted for an average of 11 percent of the total supply of crude and scrap aluminum; and 85 percent of the bauxite used in 1963 was imported.

The recovery of secondary aluminum, from 1959 to 1963, averaged 19 percent of the apparent consumption of primary and secondary aluminum recoverd. New scrap is the source of 80 percent of the secondary metal recovered.

The primary aluminum industry expanded sharply under the impetus of World War II and the Korean war—partly with the aid of Government funds and incentives. In 1940, there was one domestic primary aluminum producer, by 1963 there were seven, three of which were completely integrated from the mine to aluminum fabricating plants. Much of the primary production is consumed in semifabricating plants owned by the producers.

Since approximately 20 percent of the cost of aluminum is electric energy, the aluminum industry, has until relatively recent times, built plants near sources of low-cost hydroelectric power. However, since World War II, demand for power in industrially developed countries has increased sharply and competing industries can pay more than the aluminum industry for power. The domestic aluminum industry turned first to hydroelectric power, second to natural gas, then to lignite, and in 1957 new aluminum smelters were built near large coal deposits. Aluminum producers in many foreign countries have constructed plants in relatively isolated and thinly populated areas where hydroelectric power could be made available.

The progressive research, development, and sales policies of the aluminum producers have resulted in the displacement of many materials from their historical market by aluminum. The relatively stable price of aluminum has been an important factor in the increased usage of the metal. Industries which consume major quantities of aluminum are—Building and construction, transportation, consumer durables, containers and packaging, electrical equipment, and machinery and equipment. As applications for aluminum are developed and current markets are expanded, production and consumption of this versatile metal are expected to continue to expand at a greater rate than the national economy.

Maintenance of an adequate aluminum supply requires assured sources of alumina and electrical energy. Continuation of research on reactions in the electrolytic cell may result in a decrease in power and manpower requirements. Alloy and product research will lead to the development of new uses that will consume large quantities of aluminum.

[1] Alumina, bauxite, and recovery of alumina are discussed in the Alumina and Bauxite chapter.
[2] Commodity specialist.

780-887 O—65——3

BACKGROUND

Recognizing that alumina was the oxide of a metal, Sir Humphry Davy, in 1808, named the metal "alumium" which he later changed to "aluminum." Later the spelling "aluminium" came into general use and is still used in many countries. In the United States the simpler spelling "aluminum" was adopted.

Davy's attempts to isolate the metal were unsuccessful, but in 1825 Hans Christian Oersted produced aluminum by treating aluminum chloride with potassium amalgam. Frederick Woehler, some years later, produced an impure powdered aluminum using potassium as the reducing agent. Henri Ste. Claire Deville, in France, using sodium metal as the reducing agent, produced the first commercial quantities of aluminum in 1854. Although much research was done on lowering the cost of the sodium, aluminum was never produced by this method at a price competitive with other nonferrous metals. In 1857 aluminum was $27 per pound and the price was reduced to $17 by 1859.

In 1885 less than 300 pounds of aluminum was produced in the United States, but the discovery of an electrolytic process in 1886 by Charles Martin Hall in the United States and independently by Paul Héroult in France opened the way for a new industry. Using this new process, by 1895 production had increased to 900,000 pounds and prices had decreased from $10 to $0.59 per pound. Now, over 75 years following the discovery of the process, equipment has undergone substantial change and refinement, but the Hall-Héroult electrolytic process still is used. In 1963, when primary aluminum production was more than 2.3 million tons, the price of ingot averaged 22.6 cents a pound.

Beginning in 1954 and continuing through 1963, production of primary aluminum in the United States has exceeded that of any other nonferrous metal. The United States has been the world's leading aluminum producer except during 1934–1940, when for 5 years Germany was the leading producer. Since 1942 Canada has been the second largest producer in the free world. Estimates of production in the U.S.S.R. indicate that country has become the second largest producer in the world since 1958.

The Aluminum Company of America (Alcoa), owning bauxite, alumina, and aluminum producing facilities, was the only domestic producer from 1886 to 1940. Under the impetus of World War II, domestic aluminum capacity was expanded sharply and by 1946, two additional producers, Reynolds Metal Co. and Kaiser Aluminum & Chemical Corp., had entered the field. In 1954, the Anaconda Aluminum Co. began producing primary aluminum. In 1958, Harvey Aluminum, Inc., and Ormet Corp. (a subsidiary of Olin Mathieson Chemical Corp. and Revere Copper and Brass, Inc.) became producers of primary metal. The latest entrant in the field, Consolidated Aluminum Corp. (Conalco), a fully-owned subsidiary of Swiss Aluminum, Ltd., Zurich, Switzerland, started production of primary aluminum in 1963.

SIZE AND ORGANIZATION OF THE INDUSTRY

Figure 1 of the Alumina and Bauxite chapter illustrates the organization of the domestic industry and shows primary aluminum plant locations and capacities (including plants under construction). Data in table 1 summarize information on productive aluminum capacity existing at the end of 1963.

TABLE 1.—*Primary aluminum productive capacity, Dec. 31, 1963*

Company	Number of aluminum production plants	Annual capacity, thousand short tons
Aluminum Company of America	8	853
Reynolds Metals Co	7	701
Kaiser Aluminum & Chemical Corp	4	609
Ormet Corp	1	180
Harvey Aluminum Co	1	80
Anaconda Aluminum Co	1	68
Consolidated Aluminum Corp	1	20
Total	23	2,511

Three of the seven primary producers, with 86 percent of U.S. productive capacity at the end of 1963, were vertically integrated from mining through production of semifabricated shapes. The remaining firms also had facilities for producing semifabricated shapes. About 80 percent of the domestic production of primary aluminum is used by these 7 firms or exported. Independent producers of semifabricated shapes and affiliates of foreign producers of primary metal use most of the aluminum imported into the United States.

Data on world capacity to produce primary aluminum in table 2 show that during 1958–63 the primary aluminum industry grew much faster in foreign countries than in the United States and Canada.

Reduction plants owned or partially owned by governments, representing about 9 percent of the free world productive capacity for primary aluminum, are operated in West Germany, Norway, Spain, Yugoslavia, Taiwan, and Austria. About 80 percent of the free world productive capacity in 1963 was operated by subsidiaries or affiliates of six corporate groups: Aluminium Ltd. and its subsidiary, the Aluminum Company of Canada, Ltd. (Alcan), Reynolds, Kaiser, the two associate French companies, Péchiney-Ugine (Péchiney Compagnie de Produits Chimiques et Electrometallurgiques and Société d'Electro-Chimie, d'Electro Metallurgie et des Aciéries Electriques d'Ugine), and Swiss Aluminium, Ltd.

TABLE 2.—*World primary aluminum productive capacity, Dec. 31, 1958 and 1963*

Country or continent	Annual capacity, thousand tons		Percent increase
	1958	1963	
United States	2,194	2,511	14
Communist countries	846	1,415	67
Europe	767	1,318	72
Canada	865	905	5
Asia	106	371	250
Other countries, including South America, Africa, Australia, and Mexico	76	219	188
Total	4,854	6,739	39

In 1963, U.S. companies owned primary aluminum plants in foreign countries, or were affiliated with firms which operated primary aluminum plants in foreign countries, having about 10 percent of the productive capacity in the free world, exclusive of the United States. U.S. companies also owned or partially owned various processing facilities in foreign countries. A Swiss company owned a primary aluminum plant in the United States and several foreign primary producers owned or were affiliated with producers of various aluminum products in the United States.

GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

The aluminum reduction industry is a major consumer of electric power and uses approximately 3 percent of the domestic electric power generated. To maintain its competitive position, large quantities of low cost dependable electrical energy are a necessity for this industry. Before 1950 plants were built near sources of low-cost hydroelectric power such as the Niagara Falls area, the Tennessee Valley area, and the lower Columbia River area of the Pacific Northwest. However, aluminum consuming and other industries entered these areas, and in some instances the cost of power from new facilities was increased. Since 1950, in addition to situating plants in the limited number of places where new hydropower supplies became available, the industry has built several large plants where natural gas, lignite, or bituminous coal for thermally generated electric power are available.

As indicated by figure 1, of the Alumina and Bauxite chapter, the raw material for the primary aluminum smelters, is produced in the South Central United States in Arkansas, Texas, Louisiana, and Alabama. The reduction plants are more widely dispersed, as shown in table 3.

TABLE 3.—*Geographic distribution of aluminum reduction plants, Dec. 31, 1963*

Location	Number of aluminum reduction plants	Annual capacity, thousand tons	Percent of total
Pacific Northwest	8	722	29
Alabama, Tennessee, and North Carolina	4	414	17
Arkansas and Louisiana	3	412	16
Texas	3	385	15
Ohio, West Virginia, and Indiana	3	360	14
New York	2	218	9
Total	23	2,511	100

DEFINITION OF TERMS, GRADES, AND SPECIFICATIONS

Pig is metal initially produced by a primary reduction plant, taken directly from the reduction cell and cast into a convenient form. Pig is cast in a wide variety of sizes, but the usual commercial size is 50 pounds, with a 99.5 percent guaranteed minimum aluminum content. Use of the term "pig" in the aluminum industry was discontinued in 1960.

Ingot is a cast form suitable for working or remelting that has been poured from either a melting or alloy furnace. A common commercial size is 30 pounds and the aluminum content is 99.5 plus percent. Since 1960 the term "ingot" represents metal that previously was referred to as pig.

Potline is a number of reduction cells or pots, usually 100 to 150, connected in electrical series.

Super-purity aluminum contains a minimum of 99.99 percent aluminum.

Aluminum alloys are generally divided into two major groups: Wrought and casting. Table 4 gives the chemical composition for two alloys of each type. Unalloyed metal usually contains 99.5 percent aluminum and small quantities of iron and silicon. Even when no alloying elements have been added, the quantity of impurities present has to be controlled

carefully. Metal with over 99.5 and up to 99.85 percent aluminum is available at costs up to 3 cents per pound more than standard commercial metal. It is used where superior electrical conductivity or corrosion resistance is required. Purities higher than 99.85 percent are necessary for certain applications.

There are several acceptable methods of designating aluminum alloys. However, a 4-digit code for wrought alloys was adopted by The Aluminum Association in October 1954. The first digit indicates the major alloying ingredient. If the first digit is 1 the alloy has a minimum aluminum content of 99.00 percent. Digits 2 to 8 in the first position designate copper, manganese, silicon, magnesium and silicon, zinc, and other element, respectively; 9 is an unused series.

TABLE 4.—*Chemical analysis of some aluminum alloys, in percent* [1]

Type and number	Cu	Fe	Si	Mn	Mg	Zn	Ti	Cr	Other elements	
									Each	Total
Wrought 1100 [2]	0.20	Fe+Si 1.0		0.05		0.10			0.05	0.15
Wrought 2024	3.8–4.9	0.50	0.50	0.30–0.9	1.2–1.8	.25		0.10	.05	.15
Casting 43	.10	.8	4.5–6.0	.30	0.05	.20	0.20		.05	.15
Casting 108	3.5–4.5	1.0	2.5–3.5	.30	.03	.20	.20			.30

[1] Values are maximum unless shown as a range; aluminum is remainder.
[2] Aluminum minimum—99.00 percent.

If the alloy has a minimum aluminum content of 99.00 percent, the second digit indicates special control on impurities and the last two digits indicate the minimum aluminum content figures to the right of the decimal point. Thus, 1030 indicates 99.30 percent minimum aluminum content without special control on individual impurities.

When the first digit is 2 through 8, indicating a major alloying ingredient, the second digit indicates alloying modifications and the last two digits identify the alloy, usually by the commercial code number previously used to designate the same alloy. Thus, 2014, formerly alloy 14S, contains copper as the major alloying ingredient with no alloy modification.

Additional letters, O and F, and letters H and T with numbers, may follow the alloy digits and designate the temper of the alloy.

No uniform system has been adopted by the industry for designating casting alloys. These alloys may be designated by American Society for Testing and Materials numbers, U.S. Federal Specifications, Society of Automotive Engineers, commercial, and individual company symbols.

TECHNOLOGY

Primary Aluminum (*2, 7, 14, 17*) [3]

Primarily aluminum is produced by the electrolysis of alumina in a molten cryolite bath. Purity of the alumina used must be greater than 99.0 percent. The electrolytic reduction cell consists of a carbon-lined box containing a pad of molten aluminum which serves as the cathode, a carbon anode, and an electrolyte of molten cryolite in which the alumina is dissolved. Small quantities of aluminum fluoride are used in the electrolyte to combine with Na_2O, an impurity in alumina, to form artificial cryolite, and the melting point of the bath is lowered by the addition of small quantities of fluorspar. The anode may be either one large block of carbon or a number of small blocks of carbon. The alumina is reduced to aluminum at the cathode and carbon is oxidized to carbon dioxide at the anode.

The carbon lining, which contains the molten aluminum, is built into a steel shell. Typical dimensions of the shell are 20-feet long, 10-feet wide, and 3-feet deep. It is lined first with refractory insulation. The insulation is then lined with carbon blocks, joined by carbon cement, or a monolithic lining is prepared by baking carbon paste in place. The carbon lining usually must be replaced after 3 to 4 years.

The carbon anodes are consumed at a rate of about 1 inch of vertical length per 24 hours of operation and the method of replacement is important in regard to overall costs. There are two methods of replacing anode carbon through: (1) soderberg continuous anodes and (2) prebaked anodes.

In the Soderberg anode a reinforced rectangular steel shell, open at the top and bottom, is suspended above the furnace. Carbon paste or briquets of coke and pitch are added period-

[3] Italicized numbers in parentheses refer to items in the list of references at the end of this chapter.

ically as the anode is consumed. Current enters the anode through rows of pins inserted into the carbon mass either vertically or horizontally. The heat of the bath and the heat resulting from the electrical resistance of the carbon bake the paste or melt and bake the briquets so that at a point approximately 20 inches above the bath the carbon becomes a hard monolithic mass. The steel pins, in addition to conducting current, support the carbon mass. As the carbon descends through the hopper and is consumed, the lowest pins are periodically withdrawn and replaced at higher levels in the anode box. The optimum anode-cathode distance is maintained by raising or lowering the pins which are baked into the lower part of the carbon block. Inasmuch as the pad of molten metal builds up at approximately the same rate as the anode is consumed this adjustment is usually made only when metal is withdrawn from the cell.

In the prebaked anode system sets of 16 to 24 prebaked carbon blocks are used. The size of the blocks varies from plant to plant; in one plant the blocks are 20 inches wide, 31 inches long, 12 inches high, and weigh about 400 pounds. The blocks are supported in the bath by steel stubs or rods which conduct the current to the carbon. These stubs are inserted into a hole in the top of the finished block and anchored in place by casting molten iron around the stub. The blocks are raised or lowered separately to maintain proper position with respect to the bath and are replaced individually as they are consumed.

The Soderberg system requires less labor and, with the exception of moving the steel pins, is a continuous method of feeding anode carbon. The prebaked system results in better electrical efficiency in the reduction cell but requires fabricating and rodding facilities not used in the Soderberg system.

The molten bath or electrolyte may be as deep as 14 inches, but the anode is usually only 2 inches from the pad of molten aluminum. The resistance of the bath is sufficient to maintain an optimum operating temperature of 950° to 1,000° C. At this temperature the alumina dissolved in the bath ranges from 6 to 10 percent. When the alumina concentration drops to 2 percent, the electrical resistance of the cell increases sharply and the voltage drop across the cell increases from 5 volts to 30 or 40 volts. The phenomenon is known as the "anode effect." As soon as this condition occurs, the crust of frozen cryolite on top of the bath is broken and more alumina is added to the cell which then returns to normal operating condition.

Every 1 to 3 days the molten aluminum is removed from the cell by aspiration. Cast iron pots with airtight lids and downward sloping spouts are used. The molten metal is blended with other batches and then may be fluxed, alloyed, cast, or if the fabricating facility is nearby, transported molten to the fabricating plant.

Plants constructed since 1950 have much larger cells than were used in older plants. These cells utilize currents from 65,000 to 125,000 amperes, with the majority of plants having 80,000- to 100,000-ampere cells. The voltage drop across a single cell is 4.5 to 5.0 volts and across a potline 600 to 800 volts.

The larger cells require less manpower per pound of aluminum produced, but special problems are encountered in cells designed to use 100,000 and more amperes. The large currents cause powerful magnetic fields in the metal and bath, resulting in violent agitation. This agitation causes a fog of aluminum to be dispersed in the bath which increases the possibility of reversing the reduction reaction. Another detrimental effect is that the molten metal piles up toward the negative leads causing a variation in the anode-cathode spacing. Moreover, localized thermal effects may distort the carbon lining.

Current efficiency ranges from 85 to 90 percent; losses are principally due to physical losses of metal and reoxidation of aluminum by carbon dioxide. Owing to the electrical resistance the voltage efficiency is only 40 percent with heat being lost by radiation, and in the exhaust gases, in tapped metal, and in electrodes removed from the cell. As a result the overall energy efficiency is about 35 percent. About 7 to 8 kilowatt-hours is required in the cell per pound of aluminum metal produced. Total plant requirements are less than 10 kilowatt-hours per pound.

Table 5 summaries the raw materials used in producing 1 pound of aluminum.

TABLE 5.—*Raw materials and energy required to produce 1 pound of aluminum*

	Quantity
Alumina ---- pound	1.93
Cryolite ---- do	0.02–0.03
Aluminum fluoride ---- do	0.02–0.03
Fluorspar ---- do	.003
Anode carbon ---- do	.55
Cathode carbon ---- do	.02
Electrical energy ---- kilowatt-hours	7–8

To prevent pollution of the atmosphere, gases from the cells are passed through a collection system which removes alumina, carbon, and fluorides.

The relatively low tensile strength of commercially pure aluminum limits its use in heavy durable products. However, by alloying, cold rolling, or heat treating, aluminum

alloys with strengths approaching those of mild steels have been developed. There are more than 100 commercially-available aluminum alloys and several new alloys usually are developed each year. The alloys offer a wide variety of combinations of mechanical strength, ductility, electrical conductivity, and corrosion resistance. A small addition of manganese increases the strength of wrought aluminum. Magnesium and silicon, together or separately, give aluminum alloys with good corrosion-resistance and strengths. Copper and zinc are used to produce alloys with high strength-to-weight ratios. Small quantities of other metals such as nickel, chromium, titanium, and tin are sometimes added for grain refinement or to impart special characteristics.

The production of super-purity aluminum requires a second electrolytic step in which a cell, known as the Hoopes cell, with three molten layers is used. The bottom layer is the anode, a relatively impure aluminum alloyed with copper to increase its density. The intermediate layer in the conventional Hoopes cell is molten cryolite with barium fluoride added to give it a density greater than that of pure aluminum. The top layer, which serves as the cathode, is molten super-purity aluminum.

Secondary Aluminum (*3, 13*)

Much aluminum scrap is processed into secondary aluminum ingot without preliminary treatment. New scrap requires little or no sorting, and manual sorting of old scrap is too expensive to be widely practiced. Scrap in the form of borings and turnings is dried and the oil removed by burning. Tramp iron is removed by magnetic separators. Dross and foil also usually require treatment before being melted. From 40 to 95 percent of the scrap is recovered as metal. Low recoveries are obtained from drosses and skimmings; high recoveries from segregated sheet and clips.

Most scrap is melted in 5- to 25-ton capacity reverberatory furnaces operated on a 24-hour cycle. Important advantages of this type of furnace are its ease of mechanical charging, low flux consumption, and a melt loss of only 2 to 5 percent. The molten aluminum is protected from surface air oxidation by a layer of flux, which usually contains sodium chloride, potassium chloride, and cryolite. Other salts which may be included are calcium chloride and sodium fluoride. The melt may be refined by passing chlorine gas through the molden metal or by using reactive salts such as aluminum fluoride or sodium silicofluoride in the flux. Nitrogen is introduced to degas the melt and bring the dross and oxides to the surface.

Some scrap processing plants have dust- and fume-collecting equipment. Electrostatic precipitators and Venturi scrubbers apparently are effective in removing volatile alkali chlorides and fluorides as well as particles of aluminum, magnesium, and silicon from the exhaust gases. In small, intermittent operations, furnaces may be in the open or poorly hooded and therefore can be contributors to air pollution (*1*).

Secondary smelters consuming aluminum scrap produce specification wrought and casting alloys. Casting alloys account for most of their production. Once the scrap has been melted alloying ingredients or primary aluminum are added to bring the melt to specification.

USES

Aluminum is used in many products because of its low density, high electrical or thermal conductivity, resistance to corrosion, low neutron absorption cross-section, nontoxicity, malleability, reflectivity, nonmagnetic and nonsparking properties, or high strength-to-weight ratio. In many applications aluminum is in direct competition with copper, steel, magnesium, lead, wood, plastics, rock wool, or fiberglass.

Shipments of aluminum are usually divided into the following three major categories: (1) wrought products, such as rolled, extruded and forged shapes, (2) cast products, and (3) products for dissipative uses in which the metal loses its identity as in its use as an alloying ingredient in nonaluminum base alloys, a deoxidizer in the production of steel, or in the production of aluminum chemicals. Net shipments, classified as wrought or cast products, are shown in table 6. In addition, about 66,000 tons of ingot was shipped to government stocks in 1962 and 1963 and it is estimated that 100,000 tons has been consumed annually in dissipative uses.

About 25 percent of the aluminum consumed domestically is used for construction in such items as siding, roofing, curtain walls, flashing, insulation, windows and screening, and builders' hardware.

The transportation industry is also a major consumer of aluminum accounting for more than 20 percent of total consumption. The high strength-to-weight ratio of aluminum makes it valuable in any carrier, but this factor has been most important in aircraft. In buses and truck trailers it often accounts for 15 to 40 percent of the total weight of the vehicle. Since 1945, railroad equipment manufacturers have greatly increased their use of aluminum for trim and accessories. A few "all aluminum" passenger and freight cars have been built.

During the 1920's a number of automobiles used large quantities of aluminum, but the price and supply of aluminum were such that as automobile production increased and steel technology improved, the use of aluminum in automobiles gradually decreased until 1946 when only about 7 pounds of aluminum were used per automobile. Since then, this decreasing trend has been reversed. In 1955, an average of 30 pounds per car was used and the 1964 models contain an average of 72 pounds of aluminum per car. Major aluminum components in automobiles are pistons, automatic transmission parts, and trim. In 1963, one automobile manufacturer in the United States was producing a car powered by an engine made largely from aluminum.

TABLE 6.—*Net shipments*[1] *of aluminum wrought and cast products by producers*

[Short tons]

	1962	1963

Only in the past 30 years have marine applications of aluminum become important. During this period alloys with high mechanical strength and high corrosion resistance have been developed, and the problem of bimetallic corrosion has been largely eliminated by proper insulation. Approximately 2,000 tons of aluminum was used in the superstructure, decks and deckhouses, stack enclosures, bulkheads, and lifeboats of the SS *United States*. Many small pleasure craft are fabricated almost entirely from aluminum.

About 10 percent of the total quantity of aluminum consumed goes into consumer durable goods including refrigerators, air conditioners, washing machines, furniture, utensils, and small appliances.

Ten percent of the aluminum consumed is used in the electrical and communications industries. In most instances aluminum cable with steel reinforcing has displaced copper for cross country transmission lines. It is estimated that aluminum conductors account for 90 percent of all new transmission lines in the United States. Aluminum conductor is also used in urban distribution lines and service drops.

Aluminum containers and packaging including foil, caps and closures, and collapsible tubes account for nearly 10 percent of total aluminum consumption.

Its use in machinery and equipment, in the chemical and metallurgical industry, and miscellaneous uses consume approximately 20 percent of the total aluminum supply.

Super-purity aluminum has a number of applications including its use as a catalyst for producing high octane gasoline, as an electrical capacitor foil, and in consumer products such as automobile and appliance trim and costume jewelry.

ALTERNATE MATERIALS

If aluminum supplies were curtailed, or the price increased, steel and stainless steel, magnesium, zinc, titanium, lead, copper, plastics, fiberglass, or wood could be used in place of aluminum in applications where these materials have been used previously. Steel, stainless steel, magnesium, and zinc can be substituted for aluminum in the automotive industry. Magnesium could replace aluminum for certain components in commercial aircraft, and stainless steel and titanium may replace aluminum in jet aircraft. Fiberglass, titanium, and wood may be substituted for aluminum in small boats. Copper could replace aluminum in electrical applications and lead foil or plastics could serve as substitutes in packaging.

The increase in aluminum consumption has resulted, in part, from the decrease in the price of aluminum in relation to other metals. Historically a 1 percent decrease in the ratio of the price of aluminum to the composite price of copper, lead, and zinc has increased aluminum consumption by 1.4 percent.

SECONDARY SOURCES AND RECOVERY

The recovery of secondary aluminum, from 1959 through 1963, as reported to the Bureau of Mines, averaged 19 percent of the apparent consumption of primary and secondary aluminum recovered. The scrap from which secondary aluminum is recovered is designated as either "new scrap" or "old scrap." New scrap is generated from (1) fabricating operations such as alloying, stamping, forging, ex-

truding, machining and casting and (2) rejected semifabricated and manufactured items. Old scrap is aluminum that has been used in end products and is collected for metal recovery after the products are worn out or discarded. New scrap consumption and metal recovery data are based on quantities treated outside of the generating plant and do not include "run-around" scrap consumed in the generating plant.

New scrap is the source of nearly 80 percent of the secondary aluminum recovered. The relatively small recovery from old scrap reflects the fact that the aluminum industry is a new and growing industry. Moreover, the high ratio (4:1) of new to old aluminum scrap shows that old aluminum-containing products are not being replaced as rapidly as new ones are going into use. The tonnage of aluminum in use represents a growing reservoir of old scrap for the future.

Consumers of scrap aluminum are divided into the following four major categories: (1) secondary smelters, (2) primary producers and fabricators, (3) foundries and miscellaneous manufacturers, and (4) chemical plants. The secondary smelters accounted for about 75 percent of the scrap consumed from 1959 through 1963. During this period smelters produced an average of 350,000 tons of secondary aluminum ingot annually. Much of this was consumed in the production of castings.

As indicated by the data in table 7, small quantities of aluminum are recovered from nonaluminum-base alloy scrap and some of the aluminum recovered is consumed in the production of such alloys and also in aluminous chemicals.

RESERVES (5)

Reserves and resources of bauxite and other potential aluminum ores are discussed in the "Alumina and Bauxite" chapter.

SOURCES OF STATISTICAL INFORMATION

Data on production, shipment, stocks, and value of primary aluminum are obtained monthly from all domestic producers by the Bureau of Mines. Alumina consumption is obtained annually. The Bureau also canvasses, on a monthly basis, secondary smelters and other scrap consumers to determine stocks and receipts of scrap from which monthly consumption is calculated. Production of ingot by secondary smelters is calculated from their monthly reports of stocks and shipments. Coverage of the secondary aluminum industry is estimated at more than 80 percent. Data on the operations of the members of the Aluminum Smelters Research Institute are obtained from that association. The data on both primary and secondary aluminum are published monthly and annually; the secondary data include an estimate for full coverage of the industry.

The Bureau of the Census collects and publishes monthly data on net shipments of aluminum wrought and cast products. The Bureau of the Census also obtains monthly information on imports and exports of all forms of

aluminum. The 1958 Census of Manufacturers included statistics on employment, materials consumed, electric energy purchased, and expenditures for plant and equipment.

With the exception of 1 year, data on aluminum consumption are incomplete. In 1952, under the Controlled Materials Plan, aluminum suppliers were required to report quantities of metal shipped to different segments of the consuming industries. Since then The Aluminum Association has published, semiannually by percent, shipments of wrought products, sand castings, and permanent mold castings to different major uses, as reported by its members. Although coverage is limited to members of the Association which represent about 80 percent of the wrought products producers and a much smaller part of the casting industry, the breakdown for wrought products and sand castings is believed to be representative of the entire industry.

PRODUCTION, CONSUMPTION, AND TRADE

In 1900, aluminum was produced in only four countries, and output totaled 7,500 tons. In 1963, there were 24 producing countries, and production reached 6.1 million tons as shown in table 9. The United States with a production of 2.3 million tons, the U.S.S.R. with 1 million tons, and Canada with 720,000 tons accounted for 67 percent of the world total. As indicated in table 10 production of primary aluminum in the North American continent, compared with total world output has declined from 60 percent of the world output during 1954–58, to slightly less than 50 percent in 1963.

Statistical information on the consumption of aluminum in the United States by industries or by end products is incomplete. Total apparent consumption of aluminum, calculated from primary production and primary producers' stock changes, net imports of crude, semicrude and scrap, and recovery from scrap, is shown in table 11. These figures do not allow for stock changes at any consumption level, at secondary smelters, nor for metal going to government stocks.

During 1954–58 imports accounted for an average of 11 percent of the total supply of aluminum, and from 1959 to 1963 an average of about 10 percent of the total supply was imported. Canada, Norway, France, and Japan have been the chief sources of imported aluminum.

Prior to 1959 domestic exports of aluminum were quite small averaging only about 2 percent of the total supply during 1954–58. In 1959, about 6 percent of the total supply was exported, and in 1960, 13 percent was exported. The average for 1959–63 was 8 percent.

The tariff duties on several aluminum products, effective at the end of 1963, were as follows:

Item	Rate of duty Aug. 31, 1963	Statutory rate of duty
Unwrought (in coils)	2.5¢ per pound.	0.7¢ per pound.
Unwrought (other than aluminum silicon alloys).	1.25¢ per pound.	0.4¢ per pound.
Wrought (bars, plates, sheets, strip).	2.5¢ per pound.	0.7¢ per pound.

Source: Tariff schedules of the United States, effective Aug. 31, 1963.

[3] Aluminum content.

STRATEGIC CONSIDERATIONS

Figure 1 illustrates the degree of self-sufficiency in the United States with respect to aluminum metal. Inasmuch as most of the imported aluminum comes from Canada and the domestic production capacity is dispersed (see table 3), the strategic position of the United States with respect to aluminum metal is good. However, as discussed in the Alumina and Bauxite chapter, domestic supplies of economically competitive bauxite are limited, and in 1963 imports accounted for 86 percent of the total new supply of bauxite. Consequently, both bauxite and aluminum have been acquired in various Government stockpiles. On June 30, 1964, Government inventories of aluminum totaled 1.9 million tons, of which 1.1 million was in the national (strategic) stockpile and 0.8 million was in Defense Product Act stocks. Stocks of aluminum oxide totaled 378,000 tons, of which 200,000 was in the national (strategic) stockpile and 178,000 was in the supplemental stockpile.

The primary aluminum industry is especially vulnerable to a loss of electrical power. If the power to a reduction cell is interrupted, it will freeze in a few hours and it takes 6 to 8 days to obtain metal from the cell after the power is restored. If power to a potline is lost, it may take several weeks to reach maximum production in the entire line.

GOVERNMENT PROGRAMS

The Government, through direct financing or incentives, has encouraged expansion of the aluminum industry from the mine through semifabricating facilities. Government programs have focused on promotion of a competitive industry and have resulted in the entry of new producers and assured that part of the

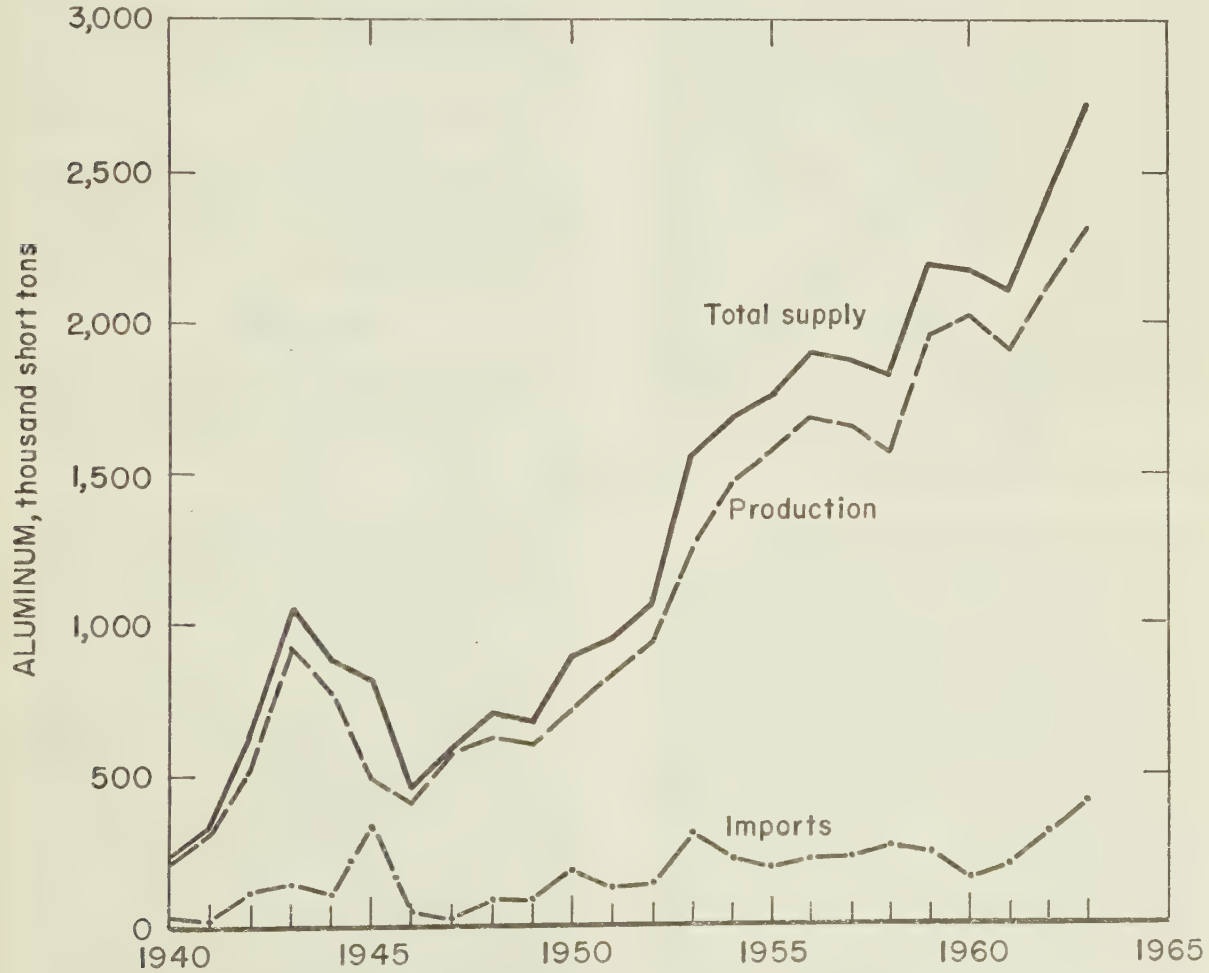

FIGURE 1.—New Supply of Primary Aluminum in the United States.

production from the new facilities would be made available to nonintegrated consumers of crude aluminum. Government policies relating to the development of power in agricultural areas have also had a profound effect on the formation and location of the industry.

Under the impetus of both World War II and the Korean War, domestic primary aluminum capacity expanded sharply. During these periods (1941–45 and 1951–52) aluminum came under the Controlled Materials Plan and the metal was distributed under a system of priorities.

After the war Government plants, which were not economically competitive, were sold and converted to nonaluminum uses. Those which could be operated competitively were sold to Alcoa, Reynolds, or Kaiser (then Permanente Metals Corp.). After disposal of the Governments plants, domestic primary aluminum capacity was 680,000 tons.

The pattern of the industry was unchanged from 1946 until the Korean War. From 1951 through 1954 inclusive, 613,000 tons of Government-aided capacity came into production. Expansion during this period differed from World War II expansion in that none of the facilities were owned by the Government and all were located near electric power sources, which would permit economic operation of the plants in peacetime. The Government issued accelerated tax amortization certificates and entered into market guarantee contracts with the companies in the early 1950's. Market guarantee contracts with Alcoa and Kaiser expired late in 1958, and the contract with Reynolds expired in 1959. The contract with Harvey Aluminum, Inc., expired in 1963.

Under these guarantees, the producers shipped 876,000 tons of aluminum to the Government between 1957 and 1963.

PRICES AND COSTS

The aluminum industry's price policy probably has been an important factor in the rapidly increasingly usage of the metal by many consuming industries. While prices of other major nonferrous metals increased between 100 to 150 percent from 1939 to 1959, the price of aluminum ingot increased only 34 percent during the same period. The average price of aluminum ingot in 1925 was 28.2 cents per pound and gradually decreased to the World War II price of 15.0 cents per pound. The first increase was in 1948, but the 1925 price was not approached until August 1957 when the postwar high of 28.1 cents per pound was reached. From 1957 until late 1963 the quoted price for aluminum ingot gradually declined to 22.5 cents per pound. In October 1963 the price was increased to 23 cents per pound.

Prices quoted at the end of 1963 for various grades of aluminum scrap clippings ranged from 11.5 to 12 cents per pound for 2075 (75S) to 15.5 to 16 cents per pound for 1100 (2S). Mixed aluminum clippings were quoted at 14 to 14.5 cents per pound. Old aluminum sheets and castings were quoted at 12 to 12.5 cents per pound, and aluminum borings and turnings were quoted at 12.5 to 13 cents per pound.

Effective September 27, 1963, quoted delivery prices for 10-ton lots of various grades of smelters' alloys ranged from 21 to 21.5 cents per pound for 380 (AXS–679) alloy containing 3 percent zinc to 29.25 to 29.75 cents per pound for 218 alloy grades. Steel deoxidizing grades ranged from 19.5 cents per pound for 85 percent aluminum (minimum) grade to 23.25 cents per pound for 95 percent aluminum grade.

One company reported the following mill costs (in cents per pound of pig) for 1953 (*23*):

Raw materials (includes alumina at cost including transportation and alloying materials)	4.71
Energy (for reduction only)	2.93
Manufacturing costs	6.43
Total	14.07

Transportation costs on shipments of pig, general administrative expense, and selling expense brought the total cost to 16.20 cents per pound of pig. The average price of pig in the United States in 1953 was 19.7 cents per pound.

RESEARCH

The high rate of growth in the aluminum industry has been maintained by aggressive marketing practices and a large and continuing research effort to develop new products and improve efficiency from the reduction cell. Industrial research covers the entire field of metal production, through the development of alloys and casting techniques, the study of protective and decorative finishes, and detailed investigations of end use applications of the metal. The producers develop technical data for their own use, as well as for the use of their customers.

Improvements in operation of the reduction cell that were under investigation, included the use of lithium fluoride in the electrolytic bath and new materials of construction for cathodes. Kaiser Aluminum & Chemical Corp. and British Aluminum Co. Ltd. developed a modified type of reduction cell which utilized refractory hard metal compounds instead of carbon as electrodes. Typical materials considered for this application were the carbides and diborides of titanium and zirconium. If the new cathode

materials and the improved electrolyte prove satisfactory, the total increase in production capacity per cell could be as high as 50 percent.

Aluminium Ltd. in Canada conducted pilot-plant studies of its process for producing aluminum from an impure metal made by direct reduction of bauxite. Aluminum trichloride was reacted with the impure metal at 1,000° to 1,200° C to form aluminum monochloride, which was subsequently cooled to about 700° C and decomposed to pure aluminum metal and to the trichloride, which in turn was recirculated. Based on the experience of operating its pilot plant, the company completed construction of a new installation at Arvida in 1963 and planned to determine capital and production costs which would be expected from large-scale operation of the process.

Another direct reduction process, developed by Péchiney of France, also was believed to be operating on a pilot-plant scale. In the French process, bauxite is partially reduced with carbon in an electric furnace, then it is further reduced with carbon to produce a mixture of aluminum and aluminum carbides. The aluminum was separated and the aluminum carbide recycled. Reynolds Metals Co. reportedly tested a direct reduction thermal process in a pilot plant of undisclosed size.

Many other methods of recovering aluminum have been proposed. Such processes include the treatment of alumina with aluminum sulfide and carbon at an elevated temperature; hydrogen reduction of alumina at above 100 atmospheres and above 400° C; reaction between alumina and aluminum carbide at 1,980° C; and electrolytic reduction of complex alumino-organic compounds such as $NaF.2Al(C_2H_5)_3$.

Direct smelting of aluminum-silicon alloys from clay has been investigated. High-purity clay is used to minimize contamination of the alloy by iron and titanium. An electric furnace with graphite electrodes has been used with a carbon reductant, which may be coke, charcoal, sawdust, hogged fuel, or mixtures of these materials. At operating temperatures pure aluminum would volatilize or react with oxides of carbon. This is prevented by the addition of silicon which alloys with the aluminum and promotes absorption of the aluminum vapors (*4*).

Methods for recovering commercial-grade aluminum from Al-Si alloys have been investigated. Experimental procedures have included leaching the alloy with a molten metal such as zinc in which the aluminum dissolves and the silicon and impurities are relatively insoluble. The zinc is then distilled from the dissolved aluminum. In the subhalide process a crude aluminum alloy is treated with $AlCl_3$ at approximately 1,000° C to produce AlCl. The reaction is reversed by lowering the temperature; pure aluminum condenses and the $AlCl_3$ vapors are recycled.

Bureau of Mines programs on aluminum have emphasized the development of processes to extract alumina from low-grade bauxite or non-bauxite materials, as discussed in the Alumina and Bauxite chapter. However, studies have been made on carbothermic reduction of domestic clays to purchase aluminum-silicon alloys, from which the aluminum could be recovered. The Bureau operated a laboratory-scale alumina reduction cell to study the fundamental physical chemistry of the electrolytic process, and the effects of changes in certain operating variables which might be interpreted in terms of plant-scale operation (*15*).

OUTLOOK

Projections of the annual rate of increase of aluminum consumption range from 6 to 10 perpent, or about 2 to 3 times the growth of the gross national product, compared with the average rate of 11 percent per year since 1900. Consumption in the United States, which was about 30 pounds per capita in 1963, is expected to grow at a slower rate than in the rest of the world, which on a per capita basis uses less than half as much aluminum as the United States.

Apparent consumption of primary aluminum, calculated from production, imports (metal and alloys, crude), exports (ingots, slabs, and crude), and changes in producers and Government stocks, provides a convenient measure of the demand for primary aluminum. The average annual growth in this measure of aluminum demand in the United States was slightly over 8 percent from 1946 to 1963. Assuming an increase of 8 percent per year, and using 1963 as the base year, apparent consumption of primary aluminum in the United States in 1968 will be 3.85 million tons, and by 1975 will reach 6.6 million tons.

The extent to which foreign trade might account for total supply of primary aluminum in a given year is not easily predicted owing to unrelated factors in the countries involved. In 1963, many domestic companies had or planned to have substantial financial interests in foreign reduction facilities, which suggests that imports will play an increasing role in the domestic market. In addition, economic trends indicate that new reduction facilities will tend to be built in areas with available low-cost power and high-grade bauxite instead of the major market

areas such as the United States. However, aluminum demand in emergent and moderately industrialized countries is expected to expand much faster than in the United States, and it is not likely that the share of imports of primary metal in the U.S. market will increase significantly.

From 1948 to 1963 imports of crude aluminum metal and alloys accounted for 11 to 24 percent of the apparent consumption of primary aluminum in the United States and averaged 14 percent per year. Assuming that imports will account for 15 percent of the projected apparent consumption, imports will be about 580,000 tons in 1968 and will reach nearly 1 million tons by 1975.

Prior to 1959 domestic exports of crude and semicrude aluminum metal were insignificant compared with the total apparent consumption of primary aluminum; however, in 1959 exports were 6 percent of the total, rose to 17 percent in 1960, and averaged about 7 percent from 1961 through 1963. Assuming that exports of primary metal will continue at about 7 percent of the projected consumption, the United States will export 270,000 tons in 1968 and 460,000 tons in 1975.

Neglecting changes in producer's inventories of primary aluminum domestic production should be about 3.4 million tons in 1968. Assuming no changes in industrial or Government stocks, domestic production of primary metal should be about 6.1 million tons in 1975. An average annual increase of 8 percent will be necessary to attain the projected output.

No plans for building new reduction plants in the United States were reported in 1963, but producers had scheduled increases in capacity of existing facilities to 2.8 million tons. Provided these expansions are completed an additional 600,000 tons of primary capacity will be needed by 1968, which might be attained through further expansion of facilities existing in 1963 and by construction of 3 or 4 new plants by 1968.

During and immediately after World War II aluminum recovered from scrap averaged about 40 percent of the apparent consumption of primary aluminum. However, from 1951 to 1963 total recovery of aluminum metal from scrap, estimated by the Bureau of Mines, has ranged between 20 and 30 percent of the apparent consumption of primary metal, the average being about 25 percent. Assuming that aluminum recovery from scrap will be 25 percent of projected consumption of primary metal, 960,000 tons of aluminum will be recovered from scrap in 1968, and by 1975 about 1.6 million tons will be recovered. It may be that the share of secondary aluminum in the over-all market will increase to more than 25 percent, owing to increasing supplies of old scrap as uses expand.

The construction and transportation industries should continue to provide the major outlets for aluminum metal through 1975; however, the relative use in these industries, which comprised 48 percent of the market in 1963, is likely to decline somewhat, because of rapidly expanding markets in other industries, especially in containers and packaging, and electrical conductors.

Free world production of primary aluminum is expected to continue to increase about 8.5 percent annually as it did in 1959–63. If this rate is maintained, 7 million tons of primary aluminum will be produced in the free world in 1968 and 12.5 million tons in 1975, compared with 4.7 million tons in 1963. The growth of aluminum production in the Communist countries probably will also increase at about 8 to 9 percent per year, reaching 2.1 million tons in 1968 and 3.7 million tons in 1975, compared with 1.5 million tons in 1963.

Intensive research accompanied by laboratory and pilot-plant studies will continue to search for new processes to recover aluminum and aluminum compounds from various aluminous ores. Economic direct reduction processes may be developed by 1968, but they are not likely to replace the Bayer-Hall facilities for many years because of the large investment in such facilities. Accordingly, the major short-term technologic changes in the industry will center upon improvements of the Hall cell operation. New reduction plants of less than 20,000-ton-per-year capacity may utilize direct reduction techniques.

PROBLEMS

Maintenance of an adequate aluminum supply requires assured ore supplies as well as continuation of research on improving processes for recovering the metal from various raw materials. The industry is faced with the problem of acquiring adequate quantities of low-cost electric power or decreasing the high energy consumption in producing aluminum.

Dusts and fumes in the effluent gases from the aluminum reduction cell represent a loss of alumina, carbon, and fluorides, and systems that collect and scrub the effluent gases represent a large capital investment.

Inasmuch as the production of aluminum is a semibatch process, the producers are faced with the high costs inherent in such an operation.

Refractories used in furnaces for melting scrap or alloying primary aluminum are attacked or penetrated by the molten metal. The recovery of aluminum from some types of scrap is quite low. Fines and dusts containing both metallic aluminum metal and aluminum oxide are discarded.

Some of the physical properties of aluminum, such as its poor strength characteristics at elevated temperatures, its softness in comparison to cast iron, lack of corrosion resistance at high temperatures or in contact with other metals, may be obstacles to the use of aluminum in special applications.

Facilities that have higher operating costs than modern plants or are poorly located with respect to markets are closed in time of surplus aluminum supplies. Closing a plant of this type results in the idling of a large capital investment and may cause some economic dislocation.

The high initial plant investment and the difficulty of obtaining an assured long-term alumina supply discourage potential aluminum producers. Small nonintegrated consumers of ingot or semifabricated aluminum, numbering the thousands, do not have assured supplies of metal.

ANTHRACITE

By J. A. Vaughan [1]

LIKE other coals, anthracite was formed from vegetable matter deposited in bogs and swamps during the Carboniferous age, which was ended by a violent series of earth movements known as the Appalachian revolution. Under the tremendous pressure and heat created by this upheaval of the earth's crust, the carbonaceous material metamorphosed into anthracite—with the volatile components being driven off in varying degrees. As a result, anthracite is a low-volatile (2 to 8 percent on a dry basis), hard, compact coal that generally breaks with a conchoidal fracture. Difficult to ignite, anthracite is long-burning, with a clean, blue smokeless flame that makes it a desirable domestic fuel.

About 95 percent of the U.S. reserve of anthracite lies in 10 counties of northeastern Pennsylvania. Other anthracites occur as relatively small deposits in Arkansas, Colorado, New Mexico, Virginia, and Washington; however, because they are classified as semianthracites, their production is included in the chapter on Bituminous Coal and Lignite. The metaanthracite field in Rhode Island and southeastern Massachusetts, which has been mined sporadically in the past, has no present economic significance.

During its long history Pennsylvania anthracite has made important contributions to the economic and industrial development of the country, both as a fuel and as a source of carbon. Approximately 5.3 billion short tons has been mined and shipped to market, and the remaining reserve (estimated as adequate to supply projected demand for several centuries) still represents one of the country's most important mineral fuel resources because of its magnitude and easy accessibility to the densely populated, highly industrialized eastern seaboard. (See fig. 1).

Peak production of approximately 100 million tons was reached in 1917 and the highest employment, about 180,000 men, in 1914. However, owing to the inroads made into anthracite's traditional space-heating markets by competitive fuels, particularly fuel oil and natural gas, production had declined by 1963 to 18.3 million tons. Since the anthracite industry had provided the base of the regional economy for so many decades, the declines in production and employment caused many serious social and economic problems for the industry and the counties comprising the producing region.

As part of its work in the fields of mineral resource conservation and development, the Bureau of Mines, in cooperation with the producing industry and others, is actively pursuing a comprehensive research program designed to improve the technology of mining, preparing, and utilizing anthracite. Through such efforts, it is hoped that production costs can be lowered and new uses found—especially in industrial and metallurgical processes—that will make the industry less dependent upon the space-heating market. Other Bureau efforts are directed toward the conservation of reserves through a cooperative Federal-State mine-water control program, which provides for the installation of deep-well pumps and the construction of surface facilities to divert surface water away from active underground workings. As an adjunct to the mine-water control program, abandoned underground mine voids are being backfilled with incombustible material to prevent surface subsidence and its attendant hazards to the public health and safety.

BACKGROUND

Early records indicate that Pennsylvania anthracite was first used by gunsmiths about 1755. In 1769, it was burned successfully in a blacksmith's forge and, in 1808, in an open grate without forced draft by Judge Fell at Wilkes-Barre. These events caused no great stir, however, because firewood was abundant and cheap and the industrialization of the country was still in its infancy.

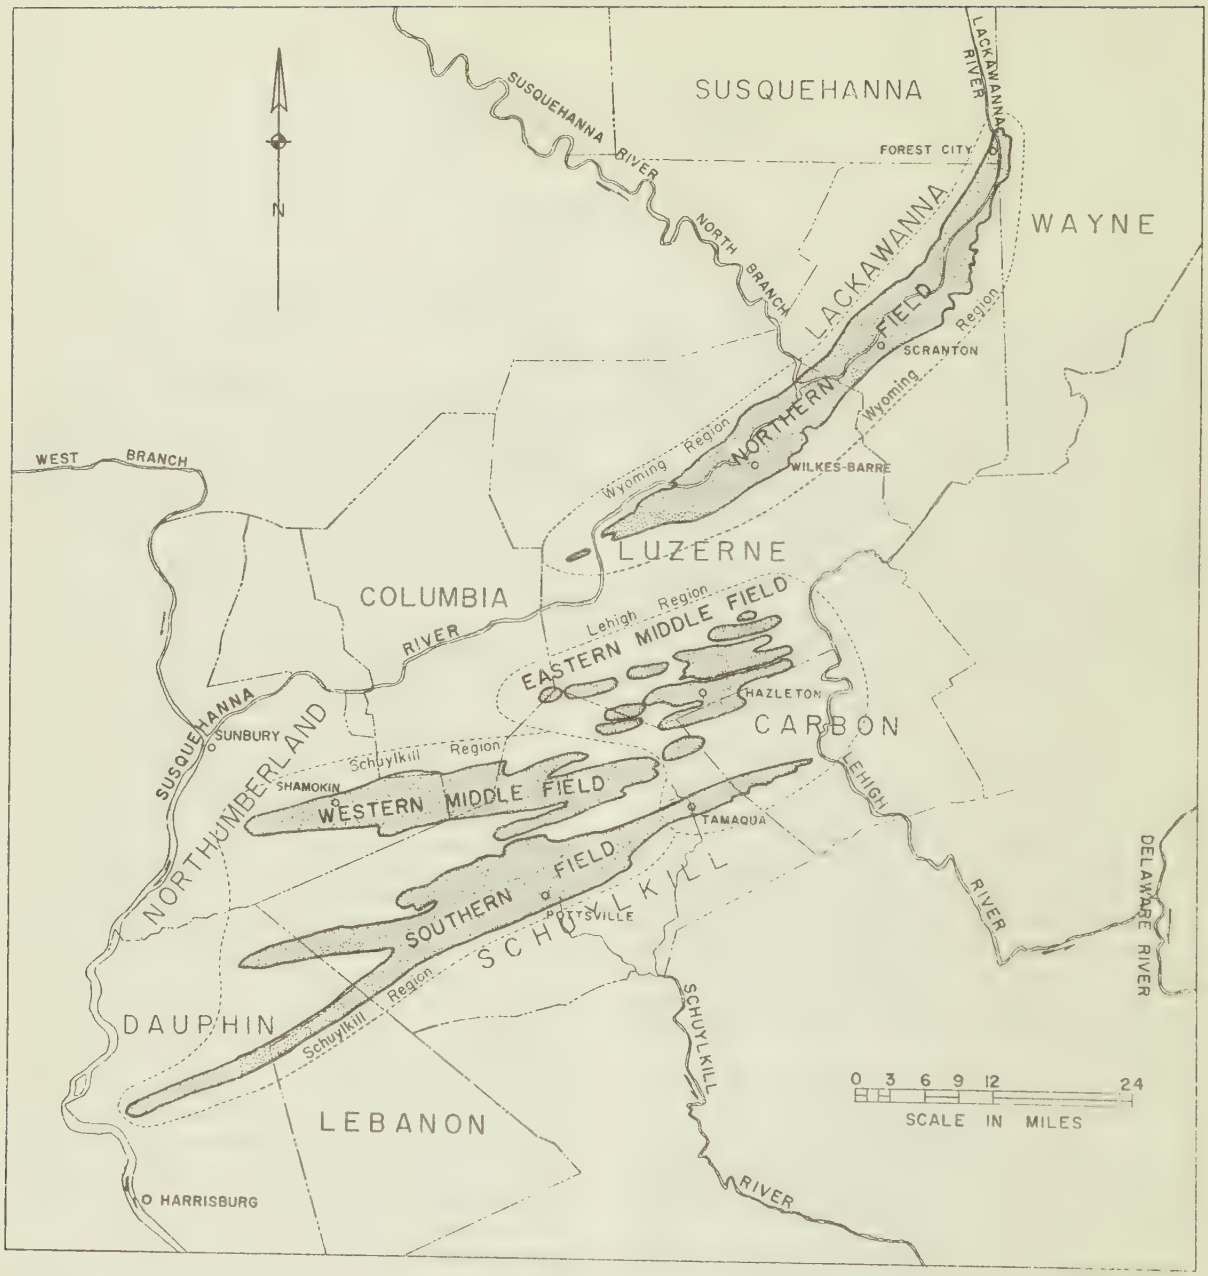

FIGURE 1.—Coalfields of the Anthracite Producing Region of Pennsylvania.

Soon after the beginning of the 19th century, charcoal and fuelwood became scarce and expensive as forests contiguous to the rapidly growing urban areas of the Middle Atlantic and Southern New England States became depleted. By 1817, a number of small anthracite mines had been opened, but it was not until 1829 that shipments were made from all the producing fields. As the highway system was crude and in some areas virtually nonexistent, the cost of transporting bulk commodities overland was prohibitive. Thus, the earliest shipments of anthracite were made by wooden "arks," or barges, which were floated down-river to market and later broken up and sold as lumber.

Seasonal variations in water flow and the dangers involved in transporting anthracite by this method, stimulated the search for cheaper and more reliable means of transporting bulky materials to distant markets. Thus, the first effort

to establish an inland canal system in the United States was engendered to stimulate demand for Pennsylvania anthracite from the Lackawanna, Lehigh, Schuylkill, and Wyoming Valleys.

A segment of the Schuylkill Canal, the first completed, was used in 1818, but it was not until 1825 that the canal was opened officially, linking Pottsville with the important Philadelphia market. Subsequently, other canals were completed that enabled anthracite to move into New York City and New England coastal cities.

The next important development in the transportation of anthracite was the creation of "feeder" lines from the mines to the canals. These lines were known as gravity "railways," with small loaded cars running downhill to the canals over wooden rails covered with strap iron. The empty cars were then pulled back to the mines by horses or mules. The first such line started operating in 1827 and connected mines to the Lehigh Canal at Mauch Chunk (now Jim Thorpe), a distance of 9 miles.

The anthracite industry also contributed another "first" to the industrial development of our country, the railroad. The famous "Stourbridge Lion" was the first steam locomotive used in this country, with the epochmaking round trip between Honesdale and the present site of Seeleyville being made on August 8, 1829. In a relatively short time thereafter all of the anthracite fields were laced by railroad trackage and the canals slowly fell into disuse.

The first statistical record of anthracite production is for 1807–20, during which 12,000 short tons was mined. With the development of first the canal system and then the railroads, anthracite production moved steadily upward until the record output of 100 million tons was reached in 1917. Peak employment, approximately 180,000 men, occurred in 1914. However, in the early 1920's heating oil began to make serious inroads into anthracite space-heating markets. By the 1930's natural gas also began to loom as a competitor, a threat that materialized fully with the spread of gas pipelines into the heavily populated cities of the Middle Atlantic and New England States after the close of World War II. By 1938, output had fallen to 46 million tons. With the advent of the war, however, anthracite production climbed rapidly, totaling 64 million tons in 1944. From this point anthracite production declined steadily under the vigorous competition of other fuels, except for a few years in which small gains were registered because of increased demand in export markets. Although higher than production in 1962, total production was only about 18.3 million tons in 1963.

SIZE, ORGANIZATION, AND GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

The 18.3 million tons of Pennsylvania anthracite produced in 1963 was the total output of 834 underground mines, 200 strip pits, 112 culm and silt banks, and 15 dredges. Run-of-mine coal from underground mines and strip pits and material from banks was cleaned and sized in 127 preparation plants (breakers and washeries). Dredge operators cleaned and sized their output as it was recovered from the streams draining the anthracite fields.

The operating structure of the anthracite industry is highly complex, ranging from the small two-man operation to large integrated units consisting of mines, pits, surface shops, and preparation plants employing several hundred. The large operating companies usually control a number of mines, strip pits, preparation plants, and in some instances, substantial quantities of recoverable coal in culm and silt banks. In 1963, the 15 largest producers accounted for about 65 percent of the total output. Many of the small operations are individual underground mines or strip pits which primarily produce run-of-mine coal for sale to preparation plants. Also, a number of the preparation plants have no mining facilities but purchase their entire input from independent producers of run-of-mine coal.

Although a few producing companies maintain their own sales organizations, the larger part of the tonnage shipped from preparation plants by rail is sold to consumers by wholesalers, dock operators, and exporters. Truck tonnages, on the other hand, are usually handled at the preparation plant and move to market as—(1) sales to consumers in the immediate vicinity of the mines (local sales); (2) sales to over-the-road truckers who dispose of the coal at retail; and (3), sales to retail dealers who dispatch their trucks to pick up loads at the plants.

The Pennsylvania anthracite beds lie in 10 counties of the northeastern part of the State: Carbon, Columbia, Dauphin, Lackawanna, Lebanon, Luzerne, Northumberland, Schuylkill, Susquehanna, and Wayne. (See fig. 1.) The Bernice Basin, lying a short distance west of the Northern field, contains a small deposit of semianthracite that is included with the Northern field for statistical purposes. The coal measures underlie a surface area of 484 square miles and are separated by geologic conditions into

four fields, the Northern (176 square miles), Eastern Middle (33 square miles), Western Middle (94 square miles), and Southern (181 square miles). Mining operations are conducted in each of the fields.

The anthracite-producing region is also divided by the coal trade into three regions: The Wyoming, which is coextensive with the Northern field; the Lehigh, composed of all the Eastern Middle field and that part of the Southern field lying east of Tamaqua; and the Schuylkill, which includes the entire Western Middle field and that portion of the Southern lying west of Tamaqua. Of the 1963 total, excluding dredge coal, 46 percent was produced in the Schuylkill region, 33 percent in the Wyoming, and 21 percent in the Lehigh. Among the fields, the Northern led with 33 percent of the 1963 total (again excluding dredge coal), followed by the Southern with 28 percent, the Western Middle with 24 percent, and the Eastern Middle field with 15 percent. Luzerne, Schuylkill, Northumberland, and Lackawanna Counties, the four largest producers in that order, accounted for 89 percent of the year's total output.

DEFINITION OF GRADES, SIZES, AND SPECIFICATIONS

Because of its characteristics, the most efficient combustion can be attained only with anthracite that has been properly cleaned and sized. Despite multimillion-dollar preparation plants capable of consistently producing a high-quality product, large quantities of poorly prepared coal were marketed during the depression years of the 1930's and World War II. The General Assembly of the Commonwealth of Pennsylvania, in an attempt to protect consumers against inferior coal, passed Act 168, approved May 31, 1947, to regulate the sale, resale, and shipment of anthracite. This act (known as the anthracite standards law) with amendments approved May 18, 1949, and September 26, 1951, not only required the issuance of a written statement as to the quality of the anthracite being shipped, and providing penalties for misrepresentations therein, but established the legal specifications for "standard" anthracite shown in table 1. Provisions of the act are administered by the Anthracite Committee, an agency of the Commonwealth.

TABLE 1.—*Standard anthracite specifications approved and adopted by the Anthracite Committee, effective July 28, 1947*

Size	Round test mesh (inches)	Percent					
		Oversize, maximum	Undersize		Maximum impurities [1]		
			Maximum	Minimum	Slate	Bone	Ash [2]
Broken	Through 4⅜				1½	2	11
	Over 3¼ to 3		15	7½			
Egg	Through 3¼ to 3	5			1½	2	11
	Over 2⅞		15	7½			
Stove	Through 2⅞	7½			2	3	11
	Over 1⅝		15	7½			
Chestnut	Through 1⅝	7½			3	4	11
	Over 13/16		15	7½			
Pea	Through 13/16	10			4	5	12
	Over 9/16		15	7½			
Buckwheat No. 1	Through 9/16	10					13
	Over 5/16		15	7½			
Buckwheat No. 2 (Rice)	Through 5/16	10					13
	Over 3/16		17	7½			
Buckwheat No. 3 (Barley)	Through 3/16	10					15
	Over 3/32		20	10			
Buckwheat No. 4	Through 3/32	20					15
	Over 3/64		30	10			
Buckwheat No. 5	Through 3/64	30	No limit				16

[1] When slate content in the sizes from broken to chestnut, inclusive, is less than above standards, bone content may be increased by 1½ times the decrease in the slate content under the allowable limits, but slate content specified above shall not be exceeded in any event. A tolerance of 1 percent is allowed on the maximum percentage of undersize and the maximum percentage of ash content. The maximum percentage of undersize is applicable only to anthracite as it is produced at the preparation plant. Slate is defined as any material that has less than 40 percent fixed carbon. Bone is defined as any material that has 40% or more, but less than 75 percent, fixed carbon.

[2] Ash determinations are on a dry basis.

An analysis of a typical chestnut-size Pennsylvania anthracite from the Lehigh region, with a heating value of 13,390 Btu per pound is as follows:

Proximate (percent)		Ultimate (percent)	
Volatile matter	3. 6	Ash	9. 3
Fixed carbon	87. 1	Sulfur	. 4
Ash	9. 3	Hydrogen	2. 1
		Carbon	85. 5
		Nitrogen	. 7
		Oxygen	2. 0

Note: Calculated on a dry basis.

TECHNOLOGY

Geology

The Pennsylvania anthracite beds occur in the Pottsville and post-Pottsville formations of the Pennsylvanian system of the Carboniferous age. The carboniferous age was ended by a violent series of movements of the earth's crust, known as the Appalachian revolution. During this period pressure developed from the southeast, causing the horizontal Carboniferous and other sedimentary formations to give way. Moving northwestward, the formations rose into mountain-forming folds, or peaks. Close to the pressure source, the folds were steep and, in some areas, overturned beyond the vertical. The continuity of the coal beds was frequently interrupted by slip-faults, or strata breaks, that displaced the bed-planes up to several hundred feet. As the distance from the pressure source increased, however, the folds became more gentle.

Under the pressures and heat generated by this vast crustal movement, the carbonaceous material in the measures metamorphosed into anthracite—with the volatile constituents being driven off in varying degrees. The clays and sands separating the beds were transformed into shales, hard sandstones, and conglomerates. In time, erosion, continuing through and subsequent to the Appalachian revolution, removed a large part of the folds and left only remnants of the original coalbeds. The anthracite measures contain from 12 to 26 minable beds, which are separated by 2 feet to 200 feet of shale, sandstones, or conglomerate. The coalbeds themselves range from a few inches to as much as 60 feet thick. Where the strata have been tightly folded, local areas have been found where a coalbed might be 100 feet thick.

Structurally the Pennsylvania anthracite fields are the remains of synclinoriums, or major downfolding of rock formations. Within the synclinoriums, minor folding formed synclinal troughs, or basins. In the northeastern part of the Northern field the coalbeds are relatively flat-lying in the center but pitch moderately to steeply toward the outcrops. In the southwestern part of the field the coal measures reach a depth of more than 2,000 feet, and have a complex system of minor folds and faults in the center with steep pitches toward the outcropline. The Eastern Middle field is composed of a number of separate, long, narrow basins in which the beds pitch steeply toward the center of each. The coal measures in the Western Middle field are characterized by steep pitches along the sides of the basins and a complex system of moderate folds and faults in the center. As the Southern field was subjected to perhaps more pressure than the others, the field is typified by pronounced folding and faulting. The coalbeds lie at extreme angles in relation to the surface, with some outcropping vertically or actually being overturned. In some places the coal has been so crushed as to run when it is mined.

Mining

The methods used in producing Pennsylvania anthracite from its various sources—underground mines, strip pits, culm banks, and streams—vary from the relatively simple suction devices employed by dredge operators to the extremely complicated underground mining systems required in extracting steeply pitching beds of thick coal.

In the earlier days of anthracite mining virtually all of the output was obtained at underground mines, since strip mining had to await the development of adequate excavating equipment. The burning equipment then in use resulted in vast quantities of pea and smaller sizes being dumped either onto culm banks or into the streams traversing the coal measures. Later, when the combustion equipment required to burn the small sizes become available, the culm banks and rivers became important sources of useable material—particularly because the initial mining cost had already been paid. Also, in recent years, the necessity of minimizing price increases occasioned by raising labor, materiel, and other costs has forced producers to close high-cost deep mines, concentrate mining at the most efficient operations, and resort to strip and bank coal for a larger percentage of their output.

As a result of the foregoing, underground mining has gradually assumed a secondary role in anthracite production. For example, in 1948 deep mines produced 65 percent of the annual output. However, as shown in table 2, produc-

tion at deep mines had dropped to 51 percent of the total in 1958 and only 37 percent in 1963. On the other hand, strip production moved from 32 percent of the total in 1958 to 41 percent in 1963, and culm-bank coal from 14 to 18 percent over the same period. Dredge production has averaged about 700,000 tons per year for 1956–65.

TABLE 2.—*Production of Pennsylvania anthracite, 1958 and 1963, by fields and source*

[Thousand short tons unless otherwise specified]

Field	From underground mines	From strip pits	From culm banks	From river dredging	Total	Percent
1958:						
Eastern Middle	264	942	532	----------	1,738	8
Western Middle	2,567	2,371	1,045	69	6,052	29
Southern	2,579	1,737	771	610	5,697	27
Northern	5,289	1,828	555	12	7,684	36
Total	10,699	6,878	2,903	691	21,171	100
Percent	51	32	14	3	100	----------
1963:

Total	6,714	7,468	3,393	692	18,267	100
Percent	37	41	18	4	100	----------

Underground Mining

The conventional systems of mining in the Pennsylvania anthracite region are—Chamber and pillar; breast and pillar; and, to a small extent, slant chute. However, in some flat, deep areas with heavy cover, part, or all, of the pillars are recovered later in "robbing" and third-mining operations.

The chamber-and-pillar method is generally used in flat and slightly to moderately pitching areas, regardless of the thickness of the coalbed. With this method, chambers are driven 24 to 30 feet wide and up to 300 feet long—leaving coal pillars 26 to 36 feet wide between the mined-out chambers to provide support for the overlying strata. This method particularly applies to the Northern field; however, where such support is not required, the pillars are subsequently recovered.

The breast-and-pillar system is used in steeply pitching areas. With this method, "breasts" (called "rooms" in flat areas) about 24 feet wide are driven up the pitch, usually on 50-foot centers, with supporting pillars being left between them. As the coal face is blasted off, some of the loose coal is allowed to accumulate in the "box," which is formed by the manways constructed on both sides of the breast as the coal face is advanced. The box, which is kept filled, thus not only provides roof support but a working platform for the miners. The loose coal is drawn from the boxes after the breast is completed and before "robbing," or pillar recovery, begins. Some operators use a 34-foot center and do not attempt pillar recovery because a major part of the pillar generally "squeezes out" when the box coal is drawn.

The latter system is one of two relatively recent advances in pitch-mining techniques that have increased safety and the percentage of recovery. By omitting the pillar-robbing phase of the pitch-mining cycle the most hazardous part of the work has been largely eliminated. The other advance has been achieved by the introduction of long-hole pitch mining, a form of longwall. In using this method, the only work performed above the "monkey heading," or return airway, is driving two narrow breasts (about 150 feet long) to the upper level and 12-foot long stubs, on 50-foot centers, above each chute. Holes about 2 inches in diameter are then drilled 100 to 120 feet up the pitch in the solid coal. The holes are then loaded and fired consecutively away from the near, shorter breast, thus providing an opening for the loose coal. The stubs are then driven to facilitate blasting and loading operations.

Aside from some experimental work, underground mechanization in the Pennsylvania anthracite region is limited by the geologic characteristics of the fields to mechanical loading

and haulage. The most common equipment used for these purposes are hand-loaded face conveyors, scraper loaders, and mobile loaders. Of the total loaded mechanically underground in 1963, 78 percent was in the Northern field (96 percent of the total produced at deep mines in this field), where the coalbeds are relatively flatter than in the others.

Strip Mining

Anthracite stripping techniques and equipment have been so improved that the depth and extent of an operation is limited almost entirely by the ratio between the overburden and the thickness of the coal bed.

Anthracite strip pits vary in size and extent from shallow excavations along a steeply pitching outcrop, which may be worked by a single small dragline, a bulldozer, and a few men to the removal of a complete synclinal trough, or basin, hundreds of feet deep and extending over several hundred acres. (See figs. 2 and 3.) The larger strippings require intricate engineering planning and working procedures, as well as the use of many large shovels, draglines, and auxiliary equipment. Excavators of over 30-cubic-yard capacity are in use, and one operator plans to install a 62-cubic-yard dragline in the near future. Auxiliary equipment used consists of drills capable of drilling 9-inch blastholes in hard rock at a rate in excess of 1 foot per minute, 70-ton-capacity off-the-road trucks, and large bulldozers and graders.

FIGURE 2.—View of Greenwood Mining Company's Deep Anthracite Strip Pit Near Tamaqua, Pa.

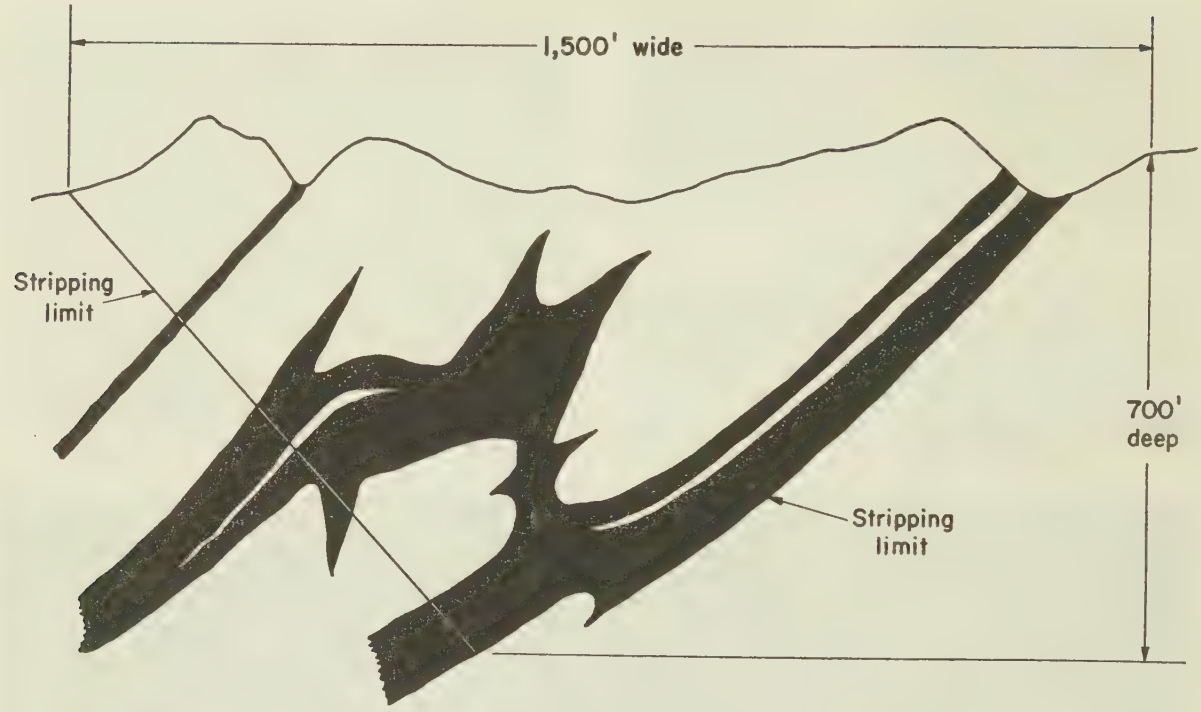

FIGURE 3.—Typical Cross Section of Coalbeds in Greenwood Stripping (fig. 2).

Culm and Silt Banks

Because of the low cost of recovery, the old culm and silt banks laid down in the early days of anthracite mining have been for several decades an important source of small-sized anthracite. Formerly a waste product of the preparation plants, the culm material is simply loaded into trucks by shovel and transported to preparation plants where it is cleaned and sized into a marketable product. The public utility industry particularly consumes large quantities of silt, ultrafine carbonaceous material that was deposited in separate banks as waste, that is not reprocessed in a preparation plant.

River or Dredge Coal

Because much of the preparation-plant wastes in the early days of anthracite mining was discharged directly into streams, or eroded into them from culm and silt banks, the beds of the Susquehanna, Schuylkill, and Lehigh Rivers, as well as many of their tributaries, eventually became covered by substantial quantities of small-sized anthracite. Since the immersion in water caused virtually no deterioration in the quality of the coal, these deposits also became valuable when combustion equipment capable of handling the finer sizes became available. The recovery of coal from the river beds started in the late 1800's with simple suction devices and dewatering screens mounted on barges, a procedure that is still followed except for the use of clamshell buckets by some operators.

Preparation

The raw feed to anthracite preparation plants, whether from deep mines, strip pits, or banks, contains varying amounts of impurities, such as slate, "boney coal" (a slaty or argillaceous material), "tramp" iron, wood, and so forth, and ranges in size from fines to massive pieces. The primary function of the preparation plant, therefore, is to break the large pieces, remove the impurities, and separate the coal into standard sizes.

The first anthracite preparation plant, locally termed "breakers," was constructed in the Southern field in 1844 and was capable of sizing 200 tons per day. During the ensuing decades, numerous cleaning, sizing, and dewatering techniques were developed—culminating in plants having capacities of cleaned, sized coal of 2,000 tons per hour, a high degree of automation, and low manpower requirements.

Virtually all coal-cleaning methods now in use are based primarily upon the difference in specific gravity of coal and its impurities. Jigs, which clean coal by rapid pulsations of water, were once widely used in the anthracite industry

but now play only a minor role in anthracite preparation. Cones, first introduced in 1921, are still in general use for cleaning larger sizes. Coal separation is achieved in the cone (which obtains its name from its overall shape) by maintaining a sand and water mixture, which is agitated by a revolving paddle in the center, at a gravity slightly higher than the coal—thus permitting the coal to float off and the refuse to sink. However, in another type of cone, similar results are achieved by setting a coal-and-water mixture into a swirling motion by water nozzles placed in the sides of the cone. Heavy-media equipment utilizing mixtures of magnetite and water has also gained wide acceptance for cleaning the pea and larger sizes.

Hydro-separators, or classifiers, using the principle of slow water currents and hindered settling, are used widely for cleaning the smaller sizes. Concentrating tables are utilized in a number of plants for cleaning the smaller coals. Also used for this purpose are launder screens, which since their introduction have been adapted to fine-coal cleaning by several operators.

For fine and ultrafine sizes (buckwheat No. 2 through 200-mesh), the anthracite industry first began to use flotation equipment about 1940, and there are a number of plants with this type of equipment. The most recent addition to the line of fine-coal cleaning equipment is the cyclone, which operates by the use of centrifugal force in conjunction with either water or a magnetite slurry.

USES

As with many other mineral commodities, definitive end-use data are relatively limited for Pennsylvania anthracite; however, uses fall into the following two broad categories: (1) As an energy fuel and (2) as a source of industrial carbon.

Anthracite is produced in a wide range of sizes (see table 1), each of which might be used for different purposes; however, some generalizations may be drawn as to size-use relationships. For instance, the sizes used for space-heating in homes may range downward from egg to buckwheat No. 2, with pea and larger being considered the hand-fired sizes. The automatic, or stoker-fired, sizes include some pea coal and buckwheat Nos. 1 and 2 (rice), while relatively large quantities of buckwheat No. 3 (barley) are used in automatic equipment for heating commercial establishments such as hotels, apartments, and office buildings. The barley not used for commercial heating and buckwheat No. 4 and smaller sizes are generally classified as industrial-purpose coals. Exceptions to these broad classifications are egg coal, most of which is used in the United States for gasmaking, and small quantities of buckwheat Nos. 1 and 2 used for industrial purposes.

Since the inception of mining over 150 years ago the space-heating market has been the largest outlet for anthracite, and until the advent of oil- and gas-burning equiment, Pennsylvania anthracite was the primary domestic fuel in the Middle Atlantic States, New England, and the eastern Provinces of Canada.

Public utilities are the second largest consumer of Pennsylvania anthracite. However, the trend in this market has been downward—dropping from about 3.4 million tons in 1957 to approximately 2.2 million tons in 1963. See table 4. While the sources of public-utility coal are not completely known, the larger part is undoubtedly high-ash fine material recovered at low cost from old culm and silt banks and from creeks and rivers.

The iron and steel industry is the third largest consumer of anthracite, using about 1.9 million tons in 1963 for the manufacture of coke, sintering iron-ore fines, pelletizing beneficiated low-grade domestic iron ores, lining pots and molds, heating, as an industrial carbon, and as a substitute for coke in foundries. In 1960, the last year for which data are available, class I railroads consumed about one-quarter million tons of anthracite, virtually all of which was thought to have been used for heating purposes.

Anthracite is used in manufacturing briquets, in bakeries, for burning cement and lime, in brick and ceramic kilns, curing tobacco, hay, and other agricultural products, in greenhouses and hatcheries, and in other applications where clean, steady heat is essential.

As a carbon, anthracite is used for a wide variety of purposes. Small quantities are used in telephones, as water and chemical filters and purifiers, in manufacturing battery cases, electrodes and other electrical or electronic equipment, carbides, and for making carburetted water gas. Anthracite ash is not only an excellent soil conditioner but is used widely in manufacturing lightweight building blocks. As a semiprecious stone, anthracite is used by local artisans to create jewelry and objects of art.

BYPRODUCTS AND COPRODUCT RELATIONSHIPS

Except for some mine rock and anthracite ash that have been used in manufacturing lightweight building aggregates and mine refuse used as fill, there are no important byproducts or coproducts of present anthracite mining.

ALTERNATE MATERIALS

The present pattern of fuel consumption in the United States has been formed by such diverse factors as the availability of a particular fuel in a given locality, the industrialist's desire to obtain fuel or power at the lowest cost, homeowners' concepts of convenience, and demand for the unique physical or chemical characteristics possessed by an individual fuel. Natural gas, fuel oil, coke, briquets, wood, and other fuels all compete with anthracite for use in the space-heating field. The most common expression for changes in fuels use are "conversion" and "replacement," which indicate, first, the adaptation of existing burning equipment to the use of an alternate fuel and, second, a change of the heating plant to one designed to burn another fuel.

Because of its physical characteristics, anthracite has advantages as a space-heating fuel not possessed by any other fuel. The cost of burning the smaller space-heating sizes is lower in many areas, on a Btu basis, than either natural gas or fuel oil. Efficient, automatic combustion equipment is available for both domestic and commercial heating purposes. Nevertheless, many consumers consider natural gas and fuel oil more convenient because the use of anthracite requires storage space and ash removal. Also, manufacturers of anthracite heating equipment have not succeeded in producing plants that can be installed as cheaply as gas and oil burners. Thus, anthracite has not only lost a major part of its space-heating market through conversions but has not captured an appreciable share of the market represented by new construction.

In industrial applications, several hundred thousand tons of anthracite are used annually in the manufacture of metallurgical coke, either displacing bituminous coal or to impart certain characteristics to the coke. The amount used annually as a substitute for coke breeze or bituminous coal in sintering and pelletizing iron-ore fines also totals several hundred thousand tons. Small quantities are charged directly to furnaces and foundry cupolas in place of metallurgical coke, while moderate amounts are used as industrial carbon for the manufacture of electrodes, carbides, and carbon shapes.

RESERVES

In estimating remaining recoverable reserves of Pennsylvania anthracite the Federal Geological Survey assumed past mining losses were 50 percent. Accordingly, the Survey placed total remaining reserves at 12,355 million tons as of January 1, 1960, and recoverable reserves at 6,178 million tons. However, in 1921, the weighted average recovery during first mining was estimated at 40.9 percent and for second mining, 24.5 percent. The residual, 34.6 percent, represented coal lost in underground mining. An additional 4.3 percent was estimated to have been lost in preparing the coal for market. Thus, in 1921, the recovery rate from underground operations was established at 61.1 percent. However, since 1921, improvements in both mining and preparation practices have reduced mining losses. Any estimate of present minable anthracite reserves would be unrealistic unless the following factors were given proper consideration: (1) The relatively rapid growth of strip mining; (2) coal recovered by dredges and from culm and silt banks, which was undoubtedly included as losses in earlier calculations; (3) the quantity of reserves that have been irretrievably lost by mine flooding; (4) the quantity of pillar coal that may be recovered or that must be left intact to support mine openings, the surface, or to safeguard active workings from adjoining, flooded mines; (5) coal lying under municipalities which have restricted mining within their jurisdictions; (6) unmined areas providing support for highways, bridges, streams, and so forth; (7) the economic feasibility of mining thin beds; and (8) the tonnage of anthracite destroyed by mine fires.

CONSERVATION PRACTICES

Improvements in mining and preparation practices since 1921 probably have reduced this estimated total loss and helped to conserve coal. The long-hole method, as an adjunct to the breast-and-pillar mining system, and improved methods of pillar recovery are examples of techniques which have increased the percentage of recovery. Similarly, modern preparation equipment, such as the heavy-media systems, recover a larger percentage of the raw-coal feed than the older types of equipment.

Important from the conservation standpoint also is the intensive development of stripping equipment and methods, since virtually 100 percent of the coalbed is recovered. Another important conservation development has been the recovery and use of anthracite from culm and silt banks and rivers. The coal recovered from these sources is the small-sized material that was formerly discarded by the preparation plants as unmarketable.

Mine water is a serious problem in the anthracite region that not only imposes heavy pumping costs upon some producers but threatens to inundate large reserves of coal. An overall approach to this problem has been provided by the mine-water control program established in 1955. The Federal and State Governments

have each contributed $8.5 million to purchase and install pumping plants and facilities to improve surface drainage. Coal-producing companies cooperate by paying operating and maintenance costs after the facilities are installed. The Federal Government is represented by the Department of the Interior, through the Bureau of Mines.

The mine-water control program has been a factor in preventing the flooding and loss of coal reserves. Through its surface-drainage improvements, the program also aids in the conservation of water resources by preventing surface water from seeping into the mines and forming acid solutions that ultimately would be pumped to the surface and contaminate the streams.

SOURCES OF STATISTICAL INFORMATION

All known producers of Pennsylvania anthracite are canvassed annually by the Bureau of Mines for data on production by sizes, f.o.b. mine values, source of coal—both by type of mining and by county, field, and region—and the number and types of mechanical equipment used in mining operations. These data, plus the information on employment collected in conjunction with the survey on coal-mining injuries, are published in the Pennsylvania Anthracite chapter of the Bureau of Mines Minerals Yearbook, volume II.

Coal-year data (Apr. 1–Mar. 31) are collected by the Bureau on shipments of Pennsylvania anthracite, by sizes, to more than 100 key cities in 20 States and Canadian Provinces. As producing companies frequently are not aware of the final destination of some shipments, wholesalers, sales agents, dock operators, and exporting firms are also canvassed. The resulting data are released annually in a Mineral Industry Survey, Distribution of Pennsylvania Anthracite, and include, in addition to the city data, statistics on exports and methods of transportation.

Monthly data on stocks and retail dealer deliveries of anthracite are obtained by the Bureau through a sample survey of a number of representative dealers. Estimates are prepared from these sample data for publication as supplements to the Weekly Anthracite Report and in the Minerals Yearbook.

In preparing weekly and monthly estimates of production, the statistical summary of monthly developments, and the Pennsylvania Anthracite chapter of the Minerals Yearbook, data are assembled from numerous sources. For instance, statistics on exports are supplied by the Bureau of the Census; on lake movement of anthracite by the Ore and Coal Exchange, Cleveland, Ohio; consumption by electric utilities, by the Federal Power Commission, and carloading data by the Association of American Railroads.

PRODUCTION, CONSUMPTION, AND TRADE

The first record of anthracite production in Pennsylvania was for 1807–20, during which 12,000 tons were shipped. Thereafter, production increased steadily until the record of almost 100 million tons was set in 1917. The production record since 1917 is outlined in table 3.

Anthracite consumption data shown in table 4 reveal the declining trend in the major use categories.

Oversea exports, primarily to Western Europe, have fluctuated widely in the past in response to wartime and postwar rehabilitation efforts, variations in ocean freight rates, costs of indigenous production, competition from Russian and other anthracites, and imports of petroleum.

Although the United States imported substantial tonnages of anthracite during strike periods and the depression years of the 1930's, the volume dropped sharply during World War II. By 1954, imports had declined to 6,000 tons and have not exceeded 10,000 tons since.

[1] Does not include exports to West Germany for use at U.S. military installations.

The U.S.S.R. has led the world for many years in the production of anthracite, with the United States running a distant second. Both of these countries are large exporters. In 1963, according to the Bureau of the Census, 3,353,000 short tons of Pennsylvania anthracite was exported, a gain of 86 percent over that of 1962, the total for which represented a gain of 26 percent over that of 1961. These figures do not fully reflect the total oversea movement of anthracite, however, because the Bureau of the Census does not include in its data coal shipped abroad for the use of U.S. Armed Forces. Based on figures furnished to the Bureau of Mines by the Association of American Railroads, 860,800 short tons was dumped at tidewater piers for shipment to West Germany in 1963 and 948,847 tons in 1962. By subtracting the Census data from these figures, it would appear that approximately 700,000 tons moved to our Armed Forces in West Germany in 1962 and about 800,000 tons in 1963.

Thus, in 1963, more than 4.2 million tons (or almost 1 ton out of every 4 produced) was exported. Although no size data were available, trade sources indicated the major portion of the 1963 export volume consisted of the larger sizes, thus helping the industry to withstand further losses in space-heating markets of the United States and Canada.

[2] Estimate.
[3] Partly estimated.

NOTE.—An undetermined amount of semianthracite is included in the figures for some countries.

STRATEGIC CONSIDERATIONS

The anthracite fields of northeastern Pennsylvania are closer than any other mineral fuel to the major markets along the Atlantic north of Maryland. Hence, to the extent of its availability, anthracite is in a favorable position to replace other solid fuels which may become scarce in these areas during periods of emergency. However, despite an increase in production of about 25 percent between 1940 to 1944, supplies of anthracite were insufficient to meet expanded demand during World War II, and the Federal Government had to institute a strict allocation program to insure equitable distribution of the available coal. Although the anthracite industry can temporarily raise output above the 1963 level by working a fuller week and stepping up production at culm and silt banks, there is great doubt that it would be able to match its performance during World War II because of the rapid decline of underground mining and the scarcity of economically recoverable stripping sites.

PRICES AND COSTS

As anthracite is primarily a space-heating fuel, producing companies and their sales representatives customarily offer discounts on f.o.b. mine prices about April 1 each year to encourage retail dealers and consumers to purchase coal during the summer months. In 1963, the discounts averaged about $1.75 per short ton on egg, stove, and chestnut; pea, $0.50 to $0.70; buckwheat No. 1, $0.25 to $0.75; buckwheat No. 2 (rice), $0.25 to $0.50; and buckwheat No. 3 (barley), $0.40 to $0.50. In past years the spring discounts had been increased at stated intervals and in such increments as to establish the winter price schedule by the beginning of the heating season. However, in 1963, the spring prices remained in effect only a few weeks as a strong demand developed during the early summer months in the United States and Europe as an aftermath to the cold winter of 1962–63.

According to data published in the December 21, 1963, issue of Saward's Journal, wholesale prices being quoted, f.o.b. mine, were as follows: Egg, stove, and chestnut, $14.50 to $15.50 per short ton, or $0.75 to $1.00 higher than on an equivalent date in 1962; pea, $11.50 to $12.50, up $1.00 per ton; buckwheat No. 1, $10.50 to $11.00, up $0.50 to $1.25. Prices quoted on buckwheat No. 2 (rice) were virtually the same as for No. 1 ($10.50 to $10.75) and were also higher by approximately the same amount. No. 3 (barley), showing a slight weakness in demand, was quoted at $8.25 to $8.50, compared with $8.15 to $8.75 in 1962.

Retail, or delivered, prices of anthracite differ widely from the wholesale prices quoted in trade journals since they include margins of wholesalers or sales agents, rail or truck transportation costs, transshipment charges, costs of unloading and storage, local sales taxes, size-degradation losses, and retail dealer margins. The retail markup also varies markedly because of differences in yard-labor costs, the larger capital required to conduct business in large cities as compared with small towns, and other economic factors.

The differences that exist in retail prices of anthracite are illustrated by the monthly reports on fuel costs released by the Bureau of Labor Statistics. According to this source, in December 1963, stove and/or chestnut was sold at an average price of $33.50 per ton in Boston, $30.09 in New York City, $29.00 in Washington, D.C., $26.20 in Philadephia, and $24.37 in Baltimore. Buckwheat No. 1, a large portion of which is used in automatic equipment, retailed at $27.56 in Boston, $24.24 in New York City, $22.95 in Philadelphia, $21.84 in Washington, D.C., and $21.26 in Baltimore.

There are no reliable data available on costs of producing Pennsylvania anthracite, either in terms of cost per ton or by type of mining.

EMPLOYMENT, WAGES, AND PRODUCTIVITY

With the long-term decline in production, employment has declined steadily in the Pennsylvania anthracite mining industry. The average number of men working daily in 1963 totaled 13,498, or 49 percent less than were employed in 1958. Since total production declined only about 14 percent over the same period, it is apparent that the industry not only closed many underground mines with low productivity rates and concentrated underground mining at the most efficient sites but, at the same time, switched to strip pits and culm banks for a relatively larger percentage of their output. As a result of these efforts, output per man-day reached a record high in each year of 1958–63, with the 6.27 tons per man-day achieved in 1963 representing a gain of about 44 percent from the 1958 figure of 4.36 tons per day.

The Bureau of Labor Statistics, U.S. Department of Labor, terminated the monthly series of data on earnings in the Pennsylvania anthracite industry with the release for August 1961. On the basis of the 8 months reported, average hourly earnings in 1961 were $2.73 and weekly wages, $96.03. However, both of these figures are now probably higher as a result of the new wage agreement signed September 1, 1964, by major producers and the United Mine Workers of America. The package agreement included direct wage increases and such fringe benefits as three paid holidays, a $25 increase in vacation pay, and a revision of payments for lunch periods. The requirement that producers pay 70 cents into the union's health and welfare fund for each ton of cleaned coal produced was not changed.

TAXES

A corollary effect of the decline in anthracite production has been evident for some years in the field of taxation. Several companies with large coal reserves have claimed that local taxes, particularly upon coal lands the owners do not expect to exploit in the immediate future, placed a heavy burden on current operations. As a result of the claims lower assessments have been granted on coal lands, in some instances, that have benefited the operating companies; however, these reductions in the taxable real-estate base have forced some municipalities to either decrease expenditures or look elsewhere for revenue. In other cases, coal lands have been forfeited to local governments, which have obtained some income by leasing acreage to small operators.

As with bituminous coal, anthracite producers, when computing income for Federal income tax purposes, are allowed a 10-percent depletion allowance to compensate them for that portion of their reserves used in current production. The allowance is calculated at 10 percent of gross income from the coal property, but not to exceed 50 percent of the net income from such property.

TRANSPORTATION

Although Pennsylvania anthracite is shipped to virtually all sections of the continental United States and to many foreign countries, its principal markets are in the Middle Atlantic and New England States areas. These States usually provide outlets for approximately four-fifths of the annual production; however, because of a sharp increase in exports, the percentage taken by these areas dropped abruptly for the 1963–64 coal year (Apr. 1, 1963–Mar. 31, 1964). Of the 15.7 million tons reported shipped during that year, 67.4 percent moved to destinations in the New England and Middle Atlantic States combined, and about 7.1 percent to all other States. Exports totaled 25.5 percent (about 1 ton of every 4 shipped), with 21.3 percent moving to overseas destinations and 4.2 percent to Canada. (See fig. 4).

As shown in table 7, Pennsylvania is the anthracite industry's largest market—taking 41.6 percent of 1963–64 coal-year shipments—followed by New York with 14.7 percent and New

Jersey with 7.9 percent. In Europe, West Germany imported about 908,000 tons of Pennsylvania anthracite during the 1963–64 coal year (including coal shipped to U.S. Armed Forces in that country), followed in descending order by France with 828,000 tons, the Netherlands with 696,000 tons, Belgium and Luxembourg with 467,000 tons, Italy with 288,000 tons, and other European countries, 91,000 tons.

Truck shipments reported to the Bureau of Mines for the 1963–64 coal year totaled only 41.6 percent of total shipments as compared with 47.3 percent in the previous year. This decline was attributable in part to an actual decrease in tonnage, but the major reason was the sharp increase in overseas exports, all of which originates as rail shipments at the mines. Neverthless truck transportation of anthracite has grown rapidly in recent years. During the 1948–49 coal year 15.7 percent was shipped to market by truck compared with 50.5 percent in 1961–62. Several factors account for this development: (1) The relative stability of the market in the producing region, (2) increased rail freight rates, (3) larger truck capacities, (4) improved highways, (5) shorter turnaround time between mine and consumer, and (6) greater flexibility in retail dealer operations.

Rail rates on anthracite are seldom based on mileage. Therefore, it is generally found that the per-ton-mile rate tends to decrease in proportion to the length of haul. However, because operating costs of trucks remain relatively constant, the per-ton-mile cost factor limits anthracite trucking to areas within a radius of roughly 200 miles of the producing fields. Thus, present north-south economic trucking limits are represented by southern Connecticut and northern Virginia. The preponderant part of the Pennsylvania truck tonnage is delivered east of Harrisburg, with the northern sections

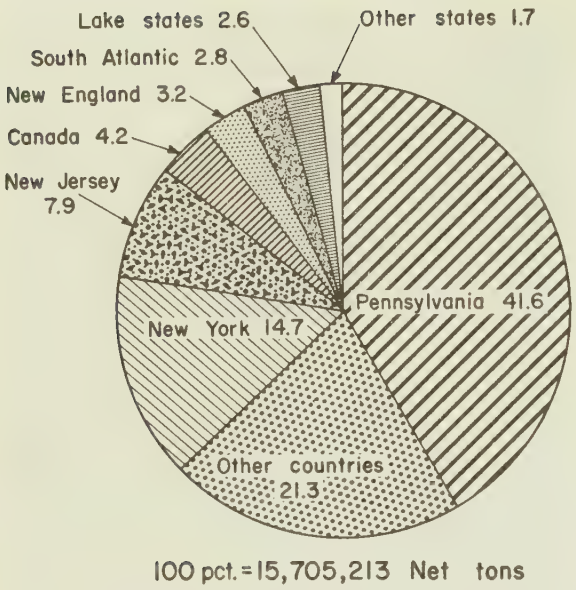

FIGURE 4.—Distribution of Pennsylvania Anthracite for the 1963–64 Coal Year, by Destination, in Percent of Total.

NOTE.—"Lake States" includes Illinois, Michigan, Minnesota, Ohio, and Wisconsin. "South Atlantic" includes Delaware, District of Columbia, Maryland, and Virginia.

of New Jersey and Delaware taking large tonnages. In New York, most of the trucked coal goes to New York City and counties in the southeastern part of the State while, in Maryland, Baltimore and the Eastern Shore are the major truck markets.

Except for occasional lake shipments to Canada, exported anthracite moves all-rail, whether to Canada or to the ports of Baltimore and Philadelphia for dumping into ocean-going vessels. Some other rail shipments are transshipped to final destinations via lake and tidewater. However, the coastal tidewater movement is virtually limited to the New York City-New Jersey area since shipments to New England, which once totaled several million tons per year, have practically ceased. The Lake trade in anthracite also has declined drastically in the past few decades, with loadings at Lake Erie and Lake Ontario docks totaling only 216,000 tons in 1963, compared with 1,322,000 tons in 1948.

GOVERNMENT PROGRAMS

The conservation of Pennsylvania anthracite reserves and the effects of mining operations upon the public health and safety are of continuing concern to both the Federal Government and the Commonwealth of Pennsylvania. In cases concerning mine water, mine fires, and surface subsidences, the Federal Government and the Commonwealth jointly provide technical and financial assistance to local municipalities and producing companies that are unable to cope with the problems involved.

To assist in maintaining an industry that would be economically capable of expanding output to fully meet defense requirements and to bolster the general economy of the producing region, the Federal Government has fostered a comprehensive research program designed to improve extraction, preparation, and utilization techniques. Research also has been conducted to develop new, or expand present, uses of anthracite—particularly in industrial and metallurgical processes. United States Armed Forces in West Germany began to purchase Pennsylvania anthracite as a replacement for German coke in the latter part of 1961. These purchases, which are designed to benefit the anthracite industry and the country's balance of payments, are expected to total about 1.1 million short tons in fiscal year 1964–65.

RESEARCH

Major anthracite research efforts have been directed primarily at reducing mining costs and creating new, or expanding old, uses. The attainment of these goals, however, has necessitated the conduct of investigations into many related fields such as the chemical and physical properties of anthracite, mining methods and equipment, the possible development of new products from anthracite, improved loading and haulage equipment, preparation techniques, and market studies.

Virtually all research in recent years has been under the sponsorship of the Commonwealth of Pennsylvania or the Federal Government. Most of the State's efforts have been coordinated by the Coal Research Board of the Commonwealth, and have been limited to special projects conducted by the Pennsylvania State University on the nature and distribution of the mineral matter content of anthracite, the effect of thermal shock on anthracite decrepitation, use of anthracite in making metallurgical coke, grindability tests, froth flotation of anthracite silts, and tests of anthracite at high pressures and temperatures. The State's efforts in the marketing field have been restricted to studies of the market-potential of Western European countries.

Since the establishment of the Anthracite Research Center at Schuylkill Haven, Pa., the Bureau of Mines has pursued a comprehensive and diversified research program on Pennsylvania anthracite. In the field of mining, much re-

search has been conducted in cooperation with producing companies. Among many projects undertaken have been the following: The development, or adaptation, of high-productivity mining machinery to moderate- and steeply-pitching beds; development of new roof-control methods to achieve a larger coal recovery and increased safety for the mineworkers; the development of a mechanized longwall mining system; the adaptation of continuous mining machines and augers to underground mining; improved loading and haulage techniques; yielding roof-support systems; hydraulic hoisting; and the hydraulic mining of anthracite at water volumes up to 300 gallons per minute and pressures up to 5,000 pounds per square inch, gage. (See figure 5.)

Conservation research conducted by the Bureau is concerned directly with investigations of the mine-water problem—including studies of the properties and characteristics of anthracite mine-water, and measures to control, or extinguish, mine and culm-bank fires. Other major, allied research efforts of the Bureau in the field of conservation are concerned with protecting anthracite reserves and the public health and safety. Conducted jointly by the Federal Government and the Commonwealth, projects in this field consist of constructing surface drainage improvements to prevent water from seeping into underground workings, where it may become acidic and ultimately contribute to stream pollution; installing deep-well pumps in abandoned mines to prevent flooding of reserves and protect workers in adjoining active mines; and, health and safety projects in which mixtures of water and incombustible material have been flushed into abandoned mineworkings to prevent, or alleviate, dangerous and costly surface subsidences. A project also was underway in 1964 to preserve on microfilm mine-maps of the anthracite producing region.

At the Anthracite Research Center, research on the utilization of anthracite has been directed primarily toward the development of large-tonnage markets. Studies of the decrepitation of anthracite under thermal shock were followed by tests of calcined (heat treated) anthracite in foundry cupolas. These tests were followed, in turn, by the successful formulation of anthracite metallurgical briquets which, after being calcined, demonstrated some properties equal or superior to metallurgical coke when tested in the Bureau's experimental blast furnace at Bruceton, Pa. Tests were also conducted at Bruceton on injecting buckwheat No. 5 and a boiler-grind anthracite into the furnace. Research conducted in cooperation with the Bethlehem Steel Co. on the permeability of blast-furnace stock columns was completed during 1964.

In attempts to discover some characteristics of anthracite that could lead to new uses, fundamental research conducted by the Bureau has included studies of mineral-matter distribution, chemical constitutents, the electrical resistivity of solid specimens, determinations of the density of selected samples of differing volatile content, surface-area measurements, and upon the effect of gamma radiation on anthracite, and on anthracite in the presence of other materials. Research into the chemical structure of anthracite was concentrated on oxidizing anthracite with nitric acid and identifying characteristics of the products obtained. Small amounts of anthracite were converted into methane in preliminary runs at 800° F and 300 to 800 pounds per square inch, gage in the miniscale hydrogasification plant constructed at the Research Center. Prior to these tests, anthracite was successfully gasified in commercial-scale Lurgi equipment.

In the field of preparation research, the Bureau has appraised various types of equipment to reduce anthracite to ultrafine particles (1 micron, or less); the production of a product containing 1 percent, or less, ash; and, the mechanical separation of anthracite-water slurries. Other efforts have included investigations of methods and equipment to obtain maximum yields of buckwheat Nos. 1 and 2 sizes when crushing chestnut coal; froth flotation; heavy-media separation; launder screens; grindability; and, washability characteristics of Pennsylvania anthracites.

Marketing research conducted by the Bureau is concerned with the production, distribution, and uses of anthracite, as well as with studies of particular markets, and the economic factors that affect fuel consumption.

OUTLOOK

Few of the components of gross national product are satisfactory for forecasting the outlook for Pennsylvania anthracite. Since anthracite is used primarily as a space-heating fuel, it might appear that such criteria as anticipated growths in population and homebuilding are valid for projecting future demand. However, neither of these reflects the individual homeowner's concept of convenience or the reluctance of speculative builders to install coal-fired equipment in homes that are sold in competition with those equipped with less expensive oil- or gas-fired heating systems. Thus, the majority of new-home buyers actually have no choice of the fuel they will use and property owners who are faced with the necessity of replacing or converting their plants are discouraged from using coal by the difference in costs of the equipment. The anthracite industry, therefore, has had little success in capturing an appreciable part of the new-home or conversion markets. As a result, consumption of the space-heating sizes in the United States has decreased at an average annual rate of about 8 percent over the last 10 years, and is expected to continue to decline in the face of continued competition from petroleum, natural gas, and electric heating.

Natural gas reached Ontario and Quebec late in 1958, and shortly thereafter exports of the large space-heating sizes of Pennsylvania anthracite began to decline. Although the decrease in exports to Canada between 1958 and 1963 was at a greater rate than in space-heating markets of the United States, the future rate of decline in exports of space-heating sizes to Canada is expected to approximate that of the United States because of similar competitive conditions in the fuel markets of the two countries. Overseas exports of the large sizes appears to be fairly bright over a short term. In 1961, exports to Europe totaled slightly over 400,000 tons but reached 2.5 million tons in 1963, excluding 861,000 tons shipped to West Germany for use by United States Armed Forces. Of the 1963 total, about 60 percent consisted of pea and larger sizes. The Armed Forces in Europe may be expected to consume about 1 million tons per year for some time. Commercial shipments of the large sizes to Europe will probably vary widely from year to year—depending upon weather conditions, availability of indigenous supplies, competition from Soviet and other anthracites, and the rapidity with which petroleum and natural gas penetrate European space-heating markets. However, trade sources indicate that, despite these uncertainties, Europe will require between 1 to 2 million tons of American anthracite annually for the next few years, thus helping the industry to absorb the anticipated losses in United States and Canadian markets.

Although total demand for Pennsylvania anthracite is expected to decline, the immediate outlook for the smaller sizes (buckwheat No. 1 and smaller) appears to be brighter than that for the larger coals. The prospects for buckwheat Nos. 1, 2 (Rice), and 3 (Barley) have been enhanced by sales of automatic anthracite-burning equipment in the commercial field (apartments, hospitals, and schools), and the decline in the consumption of these sizes will probably be below that of the larger sizes. Consumption of the smaller sizes (No. 4 and smaller) by public utilities has decreased at an annual rate of approximately 4 percent during the past 5 years. As this market is based largely upon low-cost coal obtained from river dredges and old culm and silt banks, it, too, will continue to decline with depletion of these sources. This loss, however, is expected to be offset to some extent at least by a firm, and possibly increased demand, for the fine sizes for sintering and pelletizing iron ores, as an industrial carbon, and for other miscellaneous metallurgical uses.

No new large-tonnage markets for anthracite have been developed by research in recent years; however, investigations have been made, or are in progress, on the production of high Btu gas from anthracite; the substitution of calcined anthracite briquets for metallurgical coke in blast furnaces and foundry cupolas; production of low-ash coal for nonfuel purposes, and the production of chemicals by treating anthracite with selected reactants.

World reserves of anthracite are adequate to meet future demand although some areas, such as Western Europe, may have to rely more heavily upon imports to satisfy their requirements. In the United States, reserves are considered adequate to supply any foreseeable demand despite the factors mentioned in the Reserves section, which will adversely affect the quantity of coal that can be recovered economically.

PROBLEMS

The Pennsylvania anthracite mining industry is faced with physical and technologic problems that combine to keep underground mining costs at a high level. The difficulties of mining steeply pitching beds of hard coal not only contribute directly to higher costs but also limit the use of mechanical mining and loading equipment. This, in turn, has prevented an appreciable gain in underground output per man-day. Consequently, labor still represents a large part of total mining costs and will undoubtedly continue to do so until such techniques as long-hole mining, a modification of the longwall mining method, can be more fully adapted to steeply pitched seams.

In anthracite strip mining, costs are also generally higher than for bituminous coal because the steeply pitched seams and rolling surface topography of the region complicate the problems of hard-rock overburden disposal and pit drainage. Also, efficiency of the excavating equipment is adversely affected by restrictions of working areas as pit depths increase. This latter factor is assuming greater importance since stripping sites with shallow cover are almost exhausted, and operators are being forced to use larger equipment to work deeper coal to maintain an economically favorable coal-to-overburden ratio.

Pumping expense and mine-water control measures are important cost items in many areas. With the decline in production, numerous mines have been closed and their pumps stopped. As a result, abandoned mines have become flooded and are adding to the pumping load of adjoining active mines, thus further increasing underground mining costs. Although the Federal-State mine-water control program has proved highly successful in preventing surface water from seeping into underground workings and in maintaining certain underground pools at safe levels, mine-water control and pumping costs may become so excessive, in some districts, as to cause the closure of additional operations.

Pillar failure, generally caused by concentrated mining in beds overlying each other stratigraphically, and mine squeezes caused by the shifting weight of the rock strata overlying the coal bed, has resulted in a continuing, serious problem of surface subsidence in several heavily populated areas of the anthracite region. While the Federal and State Governments have made, and are making, a joint effort to prevent or alleviate damages resulting from caving and to preserve public health and safety, the number of seams that have been mined and the length of time that anthracite mining has been conducted indicate that the danger of possible future surface subsidences will require a long-term effort by the anthracite industry and the various governmental entities involved, particularly in the Northern field.

Mine fires are also a vexing problem in the anthracite region. In addition to destroying valuable reserves, the noxious fumes thrown off by these fires pose a threat to public health. Not only are they difficult and costly to extinguish, but underground fires create problems so serious that it is frequently necessary to close active mines. Fires in old culm banks are also of concern because of their possible adverse effects on public health and safety and the destruction of scenic values.

Problems connected with preparation practices are largely concerned with a diminution of losses and quality control. Modern coal-cleaning equipment and techniques have been installed at many preparation plants, with the result that losses have been decreased. However, greater emphasis must be given to a better separation of coal from its impurities and closer control over size consist if anthracite is to compete successfully in export markets where coal size, ash content, and volatile matter are critical factors. Notwithstanding the fact that United States and Canadian markets are accustomed to an anthracite containing more ash than is ordinarily used in Western Europe, competitive conditions in North American markets make it imperative for the industry to continue to supply a high-quality product at the lowest possible price to foster a satisfactory retail dealer-consumer relationship and to retain present consumers.

The larger space-heating sizes traditionally have furnished the bulk of the anthracite industry's revenue, with some of the smaller sizes being sold below actual production cost. The continued, substantial losses to competitive fuels in the space-heating field have led to occasional imbalances in the supply of the smaller sizes. A large part of the small coal marketed for industrial purposes is low-cost dredge, or "river," coal and material recovered from culm and silt banks, but these sources are being depleted rapidly. Ultimately, a greater percentage of the total demand for these sizes must be met from underground and stripping operations. Obviously, there is an upper limit on the prices that can be obtained for the small

sizes because they compete in the various industrial markets with other carbonaceous materials. Therefore, the overriding problem of the anthracite industry is to find new, profitable outlets for the pea and larger sizes to supply the demand for the full range of sizes produced.

ANTIMONY

By Donald E. Moulds [1]

WORLD mine production of antimony was estimated at 64,000 tons in 1963 of which the free world contributed 56 percent and the Sino-Soviet bloc the remaining 44 percent. The United States requires approximately 41 percent of the world's new supply to supplement antimonial alloys regenerated each year from scrap. Other principal consumers are the industrial countries of Western Europe, Japan, and the U.S.S.R.

There is no significant domestic resource base. The domestic supply of antimony is obtained from imported ores, crude antimony, metal and oxide (44 percent), domestic mine production (2 percent), and scrap reclamation (54 percent). Domestic smelters produce primary metal and oxide from imported antimony ores and, also, as a byproduct antimonial lead from domestic and imported lead ores.

Antimony is essential as a metal for the production of antimonial lead for storage batteries plates, bearing-metal alloys, type-metal alloys and other alloys requiring its hardening, strengthening, and solidification-expansion characteristics. The oxide and sulfide enter a wide range of industrial applications such as enamels, paints, plastics, rubber, and glass manufacturing. Military uses of antimony are in ammunition primers, tracer bullets, shrapnel alloys, smoke generators, flame retardants, paints, and signal pyrotechnics.

Factors inherent in the geographical and mineralogical occurrence of antimony and those associated with demand have caused wide variances in the supply-demand balance. Because it is the world's largest consumer of antimony and presently lacks economic domestic ore supply, the United States must maintain the new supply required to support an expanding industrial use and to provide for national security.

BACKGROUND

Antimony is one of the oldest metals in continuous use by man. A vase cast in metallic antimony found among the ancient artifacts of the lower Euphrates valley discloses the fact that about 4000 B.C. the art of reducing the metal from the natural sulfide was known and practiced. Women of Biblical times used antimony as a cosmetic for eyebrow painting and recognized its medicinal qualities. Literature of medieval Europe in the 15th century alludes to liquation, precipitation, and "starring" of regulus, the refined antimony metal. Antimony was then in use in alloys for printer's type, mirrors, and bells. Precipitation of metal from the sulfide by iron is described by Ercker in the 17th century, and in the 18th century, roast-reduction procedures came into use. The early 1830's were marked by the reverberatory furnace; 1844 by the French volatilization process and 1896, by the first appearance on the market of electrolytic antimony.

Prior to the 20th century the chemical and metallurgical qualities of antimony found relatively small use. Annual consumption as measured by production was on the order of 7,500 tons. After the turn of the century consumption increased rapidly as the world industrial pace quickened and the low-cost, abundant supply of Chinese ore became available.

The wartime importance of antimony was first experienced in World War I when requirements for ammunition and antimonial-lead resulted in a shortage only partially alleviated by new production from U.S. mines and Bolivia. The postwar drop in demand caused a major antimony price depression and closure of mines unable to compete with low-cost Chinese antimony. Expansion of the auto-

[1] Commodity specialist.

mobile industry and use of storage batteries stimulated consumption in the 1930's and in turn escalated secondary recovery of antimony. The Laredo, Tex., smelter placed in operation in 1930 expanded Mexican output, and the world's largest antimony producer, the Gravelotte mine in the Republic of South Africa, initiated production in 1935.

The Japanese invasion of China in 1937 abruptly cut off this source, but expanded output from Mexico and Bolivia maintained supply for the world rearmament program and the initial action of World War II. The escalated demand of the war years again reactivated mines in the United States and expanded production of foreign mines. Bolivia was the leading supplier followed closely by Mexico. Recovery of antimony from scrap became a major domestic supply source. Antimony oxide used in flame-proofing compounds for military use became the leading end-product use and necessitated rapid expansion of domestic oxide-smelter capacity.

Demand for consumer products, especially antimonial lead for storage batteries, kept consumption relatively high in the postwar period. The Korean war stimulated consumption in 1951–52, and world production reached record levels. Domestic mine production contributed a significant tonnage, and secondary production continued at a high level.

The post-Korean adjustment of 1953 again curtailed world production and domestic production was essentially terminated. The years following, through 1962, saw world production moving upward to near record levels, secondary production continuing at a high level complementing a large domestic smelter industry supplied by imported ores and byproduct materials, and a relatively stable consumption and market price. Beginning in 1962 increased antimony consumption in the United States and other industry of countries has resulted in a world supply deficit. The unexplained withdrawal of Sino-Soviet supply from free world markets in early 1963 further aggravated the supply situation and price of metal, oxide, and ore reached record levels in 1964 as competition intensified for the available free world supply.

SIZE, ORGANIZATION, AND GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

Antimony is produced from ores and as a smelter byproduct in 23 countries located in all continental areas. The predominant sources, however, are China, Republic of South Africa, Bolivia, U.S.S.R., and Yugoslavia which together contributed 85 percent of the estimated world production during 1959–63. The mining of ore primarily for the antimony content is concentrated in relatively small areas and output of the various countries is derived from numerous small, individual operations. The major exception is the Gravelotte mine in the Republic of South Africa which has been the only source of that country's production since 1935. In addition to the ore mined, approximately 30 primary metal smelters and refineries recover antimony as a byproduct in processing nonferrous ores containing small amounts of antimony.

Recovery of antimony in the reclamation of antimonial lead scrap, primarily worn-out storage batteries, is a major source of supply. In the United States, secondary antimony represented 52 percent of the total antimony supply in 1959–63. While secondary recovery is of more significance in the United States due to availability of the proper scrap, it is also a contributing supply in other highly industrialized countries of the world.

The antimony mining industry of the United States is essentially inactive except during periods of abnormally high demand, generally resulting from wartime military requirements and disruption of normal supply. A small annual production is obtained as a byproduct of lead-silver ores and several lead smelters recover byproduct antimonial materials from processing intermediate smelter products. Byproduct antimony represents 13 percent of the primary output and 39 percent of this is derived from imported lead ores and concentrates.

National Lead Co. produces metal from imported Mexican antimony ores at the Laredo, Tex., smelter and oxide from imported African and South American ores at the Charleston, W. Va., plant. American Smelting and Refining Company produces antimonial lead and some oxide at lead refineries in Omaha, Nebr., and Perth Amboy, N.J., Sunshine Mining Co., Kellogg, Idaho, produces an impure cathode metal from locally mined silver-lead concentrates. Antimony oxide from imported ores is produced by Harshaw Chemical Co., McGean Chemical Co., and M & T Chemical, Inc., Foote Mineral Co., McGean Chemical Co., and Hummel Chemical Co. produce small amounts of powdered antimony sulfide. The total average annual production of these companies in recent years has been approximately 12,000 tons of contained antimony.

The antimony consuming industry varies widely in size and end-product utilization. More than 800 companies located in 33 States of the United States consume annually 1 ton or more. Twenty-nine companies consuming over

100 tons annually account for 49 percent of the U.S. consumption and 107 companies consuming 25 tons or more represent 72 percent.

DEFINITIONS OF TERMS, GRADES, AND SPECIFICATIONS

Antimony metal, termed "regulus" is usually marketed in units 10 by 10 by 2½ inches, variously known as blocks, bars, or pigs. Nomenclature in this regard is not fixed. Average weight is approximately 60 pounds to the bar.

Metallic antimony is sold under the brand names of the producing companies. Although a brand name represents a guarantee of antimony content, and frequently of maximum arsenic content, brand names do not denote a fixed analysis of many minor but significant constituents. Purchase contracts are usually written by the seller and include a "typical" analysis that is representative of the material sold under the specified brand name. No samples are taken before delivery; however, analysis is made at the buyer's plant to determine the exact composition of any constituents that are critical to his operation.

The leading domestic brands follow:

(1) National Lead Co.'s RMM brand, which has a guaranteed antimony content of 99.5 percent and a maximum arsenic content of 0.1 percent, and (2) National Lead Co.'s Lone Star brand, which has a guaranteed antimony content of 99.8 percent, arsenic maximum of 0.05 percent, and no other single impurity exceeding 0.1 percent.

Uses of high-purity antimony in the electronics industry led to production of antimony 99.999+ percent pure. The metal carries no brand names. Known producers are Bunker Hill Co., Kellogg, Idaho; Associated Lead Manufacturers, Ltd., London, England; and Mitsui & Co., Ltd., Tokyo, Japan.

Chemical grade ore is that which has a purity sufficient to justify its direct use in production of the oxide, chloride, and other industrial chemical compounds. To qualify as Chemical grade, an ore must have no single metallic impurity greater than 0.1 percent and maximum combined metallic impurities of 0.25 percent.

Liquated antimony sulfide, variously termed "crudum," "crude antimony," or "needle antimony," is marketed on a basis of 70 percent antimony content.

TECHNOLOGY

Geology

Generally, antimony deposits are small, discontinuous bodies having relatively simple geologic relations. Stibnite (Sb_2S_3), together with its oxidized equivalents, is the principal ore mineral. It is found with a limited suite of silicate and carbonate gangue minerals in fissure veins and replacement bodies. The deposits are apparently hydrothermal in origin. Common genetic associations are with granites, granodiorites, and monzonites; however, the enclosing rock walls may be any type traversed by the mineralizing fluids during the ore-forming process. The mineralogy of the veins and their almost invariable shallow depth suggest a low temperature of formation at near-surface positions, possibly related to the configuration of the water table at the time of deposition.

Most of these geologically simple stibnite deposits do not contain more than several thousand tons of ore; nevertheless, the world's most productive antimony mines, including those of Mexico, Bolivia, China, Peru, Yugoslavia, and Algeria are of this type. The economics of their production is often related to (1) minor recoverable values of other ore constituents and (2) locally low mining and transportation costs unrelated to the inherent nature of the deposits.

Antimony also occurs as a constituent of other metalliferous ores. This category ranges in complexity from rather simple deposits in which stibnite is a significant segment of quartz-gold veins to copper-lead-zinc sulfide bodies, in which minor antimony occurs locked within a complex crystal lattice such as tetrahedrite. Virtually all domestic mine output has been from these more complex deposits. In some ore bodies the antimony content shares the total value equally with one or more other metallic constituents of the ore. In many deposits the antimony content of the ore is so small that its presence is detected at some stage in processing so far removed from the mining operation that identity and quantitative relation to specific ore bodies is obscure.

Development, Mining, Milling, and Smelting

Because of the geologic configuration of a typical antimony deposit, entry is by a shallow

shaft or short adit, development by sill cutting in the plane of the vein, and stoping by simple overhand methods between raises driven on the footwall of the ore.

A large-tonnage open-pit mine near Stibnite, Idaho containing disseminated value in gold, antimony, and tungsten was in production before 1953, demonstrating that antimony mining need not be totally confined to small-scale unmechanized methods (*1*).

Commercial ores range from low grades, containing only 1 or 2 percent antimony, to high grades that approach the theoretically pure limit of stibnite, 71.5 percent antimony. The lower grade ores are hand sorted or milled by flotation or simple tabling methods. Owing to friability of stibnite, jigging and dense-medium processes entail prohibitively high slime loss.

Ores and residues containing 5 to 25 percent antimony may be treated directly by roasting to yield the volatile trioxide or the stable, nonvolatile tetroxide. Temperature and quantity of available oxygen determine the kind and relative quantity of the oxide produced. Volatilization roasting may be conducted as an ore concentrating and intermediate smelting process or as a refining method for producing a commercially marketable end product.

Ores containing 45 to 60 percent antimony often are liquated to increase the Sb_2S_3 content, to free the antimony sulfide from associated gangue, and/or to make a directly marketable product. The ore or concentrate is heated in a crucible or reverberatory furnace to a point above the melting point but maintained below the volatilization temperature of stibnite. The fused sulfide descends by gravity through the ore mass and is tapped and collected in a lower container. The resulting material, termed "crudum" or "crude antimony," is used directly in many military and industrial processes (*2*, *4*).

Antimony metal, termed "regulus," is recovered from the trioxide and tetroxide produced in volatilization and dead roasting, from liquated sulfide, from intermediate grades of ores by direct smelting, and from slags and residues produced in refining other metals such as lead. Oxides are reduced most conveniently in reverberatory furnaces, using coke and a suitable flux such as soda ash.

Rich sulfide ore and crudum are reduced to metal by iron precipitation in some localities, as in England, Hungary, Japan, and Mexico (*5*). Fine iron scrap is added to molten antimony sulfide, yielding metallic antimony and iron sulfide. Fluxing produces a low-density iron matte from which the metallic antimony separates by gravity.

Water-jacketed blast furnaces are being used in several modern plants to reduce intermediate (10 to 30 percent) grades of partly oxidized sulfide ores, residues, mattes, and slags. Briquetted flue dust can also be used as a blast-furnace charge. Best conditions are low blast pressure, high smelting column, low antimony content, and proportionally low coke content. Considerable slag is formed and is desirable as it tends to reduce volatilization losses.

At the world's largest antimony smelter, Laredo, Tex., blast-furnace reduction is used prior to reverberatory treatment in producing metal and commercial oxide from oxidized, relatively low grade Mexican concentrates.

The Sunshine Mining Co., Coeur d'Alene district, Idaho, recovers impure cathode metal by electrolysis of an antimony-enriched solution obtained from leaching tetrahedrite concentrate.

Antimony is recovered as a byproduct at lead refineries from processing intermediate metallurgical products that contain antimony as an impurity.

Historically, the purity of antimony has been judged by the appearance of radiating crystal patterns on the surface of the cast. Although impurities may impede this crystal development, the "starring" of the surface is more closely related to the rate of cooling. The false significance of the stars is so firmly established in the minds of antimony buyers, however, that the refiner finds it necessary to star the surface of his castings by slow cooling under cover of a layer of slag (*4*).

USES

Antimony is a brittle, silvery-white metal having a specific gravity of 6.68 and a melting point of 630° C. It is similar in many properties to arsenic and bismuth. Antimony is used both in its metallic form and in the form of compounds, oxides, and salts. Only a small amounts of antimony is used in pure metal end-products. The principal use of metal is as an ingredient in many lead-base alloys and in alloys of other metals. In its nonmetallic form, antimony has a wide range of industrial applications (*3*).

Antimony alloyed with lead finds industrial use in battery grids, chemical pumps and pipes, tank linings, roofing sheets, and cable sheaths. The function of antimony in these antimonial alloys is to increase strength and inhibit chemical corrosion. In antifriction bearings the antimony forms hard crystals of SnSb that are imbedded and dispersed through a soft alloy such as $SnCu_3$ or soft lead. Antimony increases hardness, minimizes shrinkage, permits sharp definition, and lowers the melting point

of printers' type metal. Precision duplication, durability, metallic beauty, and economy make antimonial alloys desirable for decorative castings.

The oxide of antimony, Sb_2O_3, is used extensively in metalware and ceramic enamels and as a white pigment in paints. The trioxide is also a glass former, like silica, and is valued for peculiar light-transmitting characteristics. Various chemical compounds yield pigments of black, vermilion, yellow, and orange. Infrared-reflecting characteristics of a certain antimony sulfide pigment have led to its use in camouflage paints. The pentasulfide of antimony is used in the rubber industry as a vulcanizing agent. The textile industry uses the oxide with chlorinated paraffin and lime as a finishing additive to fibers. The role of the Sb_2O_3 is one of filtering out the fiber-destroying, ultraviolet wavelength of sunlight.

Large quantities of antimony trioxide or trichloride in an organic solvent are used to make military fabrics fire resistant. Flames accompanying initial combustion are restricted or extinguished by chemical reactants released by heat from the treated fabric.

Antimony is used in various ammunition components. Alloyed with lead it hardens small-arms bullets. Tracer bullets have a recess in their base containing a light-emitting antimony sulfide mixture that permits visual tracking of the projectile. Burning antimony sulfide creates a dense white smoke that is used in visual fire control, in sea markers, and in visual signaling. A small but critical tonnage of antimony sulfide is used annually in percussion type ammunition primers as a friction element and heat-transfer medium. High-purity antimony metal is used in increasing amounts in intermetallic compounds by manufacturers of electronic semiconductors and thermoelectric devices.

Industrial consumption of primary antimony in the United States is shown in table 1.

TABLE 1.—*Industrial consumption of primary antimony in the United States, by class of material produced*

[Short tons, antimony content]

Product	1954–58 (average)	1959	1960	1961	1962	1963

BYPRODUCTS AND COPRODUCT RELATIONSHIPS

All antimony from domestic sources is a byproduct or coproduct of mining, smelting, and refining other metals and ores that contain relatively small quantities of antimony. Because of the metallurgical affinity of antimony for lead the byproduct material is segregated and extracted at primary lead refineries.

ALTERNATE MATERIALS

Antimony has no properties that make it indispensable, but it has technologic advantages in many areas of application. Mercury, titanium, lead, zinc, chromium, tin, and zirconium may displace antimony in paints, pigments, and enamels. Tin may substitute for antimony in cable sheathings, calcium in battery plates, bismuth in type metal, zinc in decorative cast-

ings, organic synthetics in fireproofing textiles, and copper in bearing metal. However, the choice of a raw material is an economical choice as well as a technological one. Antimony has always been a relatively cheap metal, substituting for more expensive ones. The specific uses, and the extent to which antimony is used, is an economic equilibrium position. With shifts in prices of antimony and of replacing metals there is a corresponding shift in use pattern.

SECONDARY SOURCES AND RECOVERY

Over 50 percent of the annual domestic supply of antimony is derived from scrap. Secondary antimony recovered at 194 plants in 1963 totaled 20,803 short tons valued at $13.5 million at the domestic price of primary metal. Recovery of antimony from battery-plate scrap comprised 60 percent of the total secondary output. Type-metal scrap yielded 3,400 tons of antimony. Bearing-metal scrap contributed most of the remaining feed material. Essentially all secondary antimony was recovered as regenerated antimonial alloys.

The United States has a large quantity of antimonial alloys now in use that will eventually return as scrap to be reprocessed. Consideration of the number of automobiles in use leads to a conservative estimate of 150,000 tons of recoverable antimony available from this source.

RESERVES

The Rocky Mountain and west coast areas of the United States contain numerous small, discontinuous antimony deposits but only a few have been mined successfully when price was exceptionally high or war incentives in effect (*6*). The Federal Geological Survey estimates that ore of this type which could be economically mined largely or entirely for antimony at a required antimony price of 60 cents per pound, contains 55,000 short tons of metal. About half of this resource is in the Yellow Pine district of Idaho.

Currently the only commercial source of antimony in the United States is as a minor by-product associated with the mining and treatment of base and precious metal ores and ultimately recovered at lead smelters. The Geological Survey estimates this type of antimony resource to be 55,000 tons of recoverable metal. The U.S. reserve of mineable antimony at conceivable peacetime prices is 110,000 tons.

There are few commerical deposits of antimony in the world of sufficient magnitude and geological continuity to permit development of significant reserve ore in advance of mining. The deposits found in China, Bolivia, and Mexico are individually of small extent and production is conducted as a small-scale enterprise. The Consolidated Murchison operation in the Transvaal, Republic of South Africa, and the Yellow Pine deposit in Idaho are notable exceptions wherein the mineralized zone is sufficiently large to permit a planned program of mine development and production. World reserves are therefore mainly estimated, and classified as inferred reserves, on the basis of past production, knowledge of area geology, and potential for extension of known ore shoots and new discoveries.

The inferred antimony reserves of the world that are mineable at a price of 60 cents per pound or less are estimated to contain 4.4 million tons of metal. The free world area possesses 1.8 million or 41 percent and the Sino-Soviet bloc, the remaining 2.6 million tons.

Bolivia possesses the largest reserve of antimony in the free world area with an estimated 450,000 tons of contained antimony. Reserves in other countries are as follows: Republic of South Africa, 275,000 tons; Mexico, 225,000 tons; Turkey, 140,000 tons; Australia, 110,000 tons; Yugoslavia, 110,000 tons and Peru, 70,000 tons. Algeria and Canada have an estimated 55,000 tons and collectively the other free world countries contain 200,000 tons.

China is conservatively estimated to contain 2.2 million tons of contained antimony in reserves centered in Hunan Province and has by far the largest antimony resource in the world. Reserves of the U.S.S.R. are estimated at 275,000 tons; Czechoslovakia, 55,000 tons; and Hungary, 25,000 tons.

CONSERVATION PRACTICES

The high volatilization losses attending ore smelting are for the most part compensated by recirculating the entrapped flue dusts.

Lead smelters recover antimony metal, oxide, and antimonial lead from intermediate smelter products, such as slags, drosses, flue dusts, and residues generated at copper, lead, tin, and tungsten smelters.

Users of antimonial alloys, such as battery, bearing, and type-metal manufacturers recirculate new and used scrap metal. Primary refineries use varying amounts of scrap in addition to ores, concentrates, and intermediate smelter products.

SOURCES OF STATISTICAL INFORMATION

Data on production, consumption, and stocks of primary antimony are collected and tabulated quarterly by the Bureau of Mines. The Department of State through its Foreign Service reports furnishes statistics relating to the antimony industry in foreign countries. There are numerous foreign publications that give fragmental statistics on foreign production and consumption. Import and export statistics are obtained from Department of Commerce, Bureau of the Census.

PRODUCTION, CONSUMPTION, AND TRADE

World production of primary antimony is approximately 60,000 tons annually. Of this total China is the leading producer followed by Republic of South Africa, Bolivia, U.S.S.R., Mexico, Yugoslavia, and Turkey. The free world contributed about 60 percent in 1963 and the Sino-Soviet bloc the remaining 40 percent. This supply is augmented in the industrialized countries by reclamation of antimonial scrap. Of the countries in the world that produce antimony ores, only a few have exportable surpluses. Some approach self-sufficiency, whereas others must supplement their domestic output with imports of varying quantities of ore, metal, and oxide. Many countries produce no antimony and depend entirely upon imports to satisfy domestic requirements. The United States requires over 20 percent of the world's primary output. Other principal consuming countries are United Kingdom, U.S.S.R., France, Belgium, Japan, West Germany, and Italy.

Yearly smelter production in the United States is about 33,000 tons including 21,000 tons of antimony in alloys recovered from scrap. Of the 12,000 tons of primary smelter output, approximately 75 percent comes from imported ores and concentrates and 25 percent from by-product materials segregated in refining lead bullion and other intermediate metallurgical products derived from both foreign and domestic ores.

Industrial consumption of antimony in the United States is approximately 36,000 tons. Of this some 55 percent is recovered from scrap and reused in the form of antimonial lead. An additional 4 percent is recovered at lead primary smelters largely in the form of antimonial lead. The remaining 41 percent is recovered from antimony ores, of which 70 percent is derived from domestic smelter production, and the remainder is imported metal and oxide. The salient statistics of domestic antimony are shown in table 2.

In recent years China, Republic of South Africa, Mexico, and Bolivia have been the major suppliers of ore to the world's industrial areas. Mexico and the Republic of South Africa are the major suppliers of ore to the United States with each contributing about 40 percent of the total. South America, principally Bolivia, contributes essentially all of the remaining 20 percent. Metal and oxide imports come chiefly from Yugoslavia, United Kingdom and Belgium-Luxembourg. Both the United Kingdom and Belgium-Luxembourg have large smelter capacity, fed entirely by imported ores. They produce metal and oxide primarily to supply internal and European needs, but surpluses are sold in the U.S. market. Yugoslavia, however, has an ore reserve base that supplies its smelters.

Imports of all categories of antimony totaled 17,800 tons in 1963 of which approximately 56 percent was as antimony in ore for domestic refining, 30 percent was as refined metal and 14 percent as refined antimony oxide. Exports of antimony constitutes a relatively insignificant tonnage usually in the form of metal and alloys in crude form.

TABLE 2.—*Salient antimony statistics*

[Short tons]

	1954–58 (average)	1959	1960	1961	1962	1963

World: Production	54,400	58,700	58,800	57,400	58,700	61,100

[1] Includes primary content of antimonial lead produced at primary lead smelters.
[2] Includes primary content of antimonial lead produced at primary lead smelters and antimony content of alloys imported.

Ore and concentrates enter the United States duty free. Imports of metal are dutiable at the rate of 2 cents per pound; oxide, 1 cent; and liquated sulfide, one-quarter cent per pound.

SELF-SUFFICIENCY AND STRATEGIC CONSIDERATIONS

About 88 percent of the U.S. smelter output of primary antimony is derived from imported antimony ores and concentrates. An additional 6 percent is recovered from foreign metalliferous ores and intermediate smelter products at domestic lead refineries. Thus, it is evident that domestic smelters are over 93 percent dependent on foreign ores. Moreover, U.S. dependency does not end with the acquisition of smelter feed. In 1963, 45 percent of the domestic supply of metal, oxide, and sulfide was imported. In summary, approximately 93 percent of the total supply of primary antimony available in the United States in 1963 originated in foreign ores.

The two factors that combine to classify antimony as a strategic material are (1) the nearly complete dependency of the United States on foreign supply and (2) important military uses in flameproofing compounds, camouflage and fire-retardant paints, ammunition components, and bearings and batteries.

The erection of the Laredo, Tex., smelter in 1930 and the restriction of Chinese shipments after the Japanese conquest in 1937 shifted the source of U.S. imports of ore chiefly to Mexico, where concentrates are now transported by rail. Expansion of mining in Bolivia during World War II further strengthened the U.S. ore supply position from Western Hemisphere sources. However, the large supplementary requirements for antimony in metal and oxide, as well as contributory quantities of ore, continue to come from distant overseas sources.

GOVERNMENT PROGRAMS

Under various congressional authorizations in times of national need the Government has stockpiled antimony, controlled prices, allocated supply, and explored for domestic ore deposits. During World War II, the Reconstruction Finance Corporation and the Metals Reserve Company procured stocks of strategic and critical materials, including antimony, from China, Mexico, and Bolivia. Under the Strategic Minerals Act, the Bureau of Mines successfully conducted ore-research projects that augmented domestic antimony resources. The Office of Price Stabilization administered pricing during the Korean conflict, and the Defense Minerals Exploration Administration was inaugurated to grant loans to private industry for approved exploration.

Government inventories of antimony totaled 52,985 tons on June 30, 1964, of which 30,275 tons was in the national (strategic) stockpile, 444 tons in CCC stocks, and 22,226 tons in the supplemental stockpile. Redetermination of stockpile objective under the Strategic Minerals Act by the Office of Emergency Planning in 1964 resulted in approximately 50 percent of this inventory being declared surplus to the mobilization requirements of the United States. Under Public Law 88–615, signed by the President on October 2, 1964, sale of 5,000 tons of this surplus was authorized to assist in alleviating a developing industrial supply shortage. The initial sale to domestic producers and consumers was made in November 1964 and the remainder offered in subsequent sales in late 1964 and 1965.

PRICES

Since 1900, the market price of antimony has been characterized by abrupt fluctuations due to (1) the wide difference between peacetime and wartime demands, (2) availability of low-cost Chinese antimony sufficient to supply a large portion of peacetime demand, and (3) the high-cost incentive required to meet wartime demand. Price has thus seen a low of 4 cents per pound in 1922 and a high of 52 cents in 1951.

The most recent low price for 99.5 percent, domestic-brand metal f.o.b. New York in bulk was 31.5 cents per pound established in February 1958. An increase to 34.75 cents in April 1961 was held until January 29, 1964. The developing shortage of metal throughout the free world then initiated a succession of price increases to a quoted price of 45.75 cents per pound in early October 1964.

The scarcity of ores for smelter feed both foreign and domestic has resulted in a major price increase in relation to the stability prior to early 1963. Imported ores have increased from a range of 16 to 24 cents per pound of contained antimony, dependent on impurities contained and grade, to a early October 1964, quoted range of 41 to 47 cents per pound delivered in New York. Antimony trioxide priced at 30 cents per pound in early 1963 had risen to 60 cents per pound delivered in carload lots by early October 1964.

TAXES

Depletion allowance to domestic antimony miners is 23 percent. Domestic companies owning foreign antimony mines that are an integral

part of their domestic facilities may receive a 15-percent depletion allowance.

TRANSPORTATION

Transportation cost is a limiting consideration in many antimony mining districts of the world, often representing more than one-third of total value of the concentrate, especially during periods of abundant supply. Estimated cost to move a ton of Bolivian antimony ore concentrates from the millsite to New York is $57. A ton of concentrates from Consolidated Murchison mines in the Republic of South Africa can be shipped to New York for approximately $42 per ton. Average gross value of a ton of antimony concentrates early in 1959 was approximately $135 but by late 1964 it had increased to about $550. Low-grade Mexican ore is shipped exclusively by rail to the National Lead Co. smelter at Laredo, Tex. Bolivian ore comes to the United States from the Chilean port of Arica and the Peruvian port of Mollendo, then by sea freight to the port of entry. The Republic of South Africa ore is freighted by rail to Lourenço Marques in Mozambique and by ship to Liverpool, Portsmouth, and New York.

RESEARCH

Research by the antimony producing industry primarily concerns the development and expansion of markets. In a project sponsored by a domestic mining company, Battelle Memorial Institute has recently done notable work on developing indium-antimony and aluminum-antimony semiconductors and on the infrared transmission characteristics of antimonial glass. Two domestic producers are now experimenting in the production and characteristics of superpure antimony metal for the electronics industry.

Research by the consuming industry is more specialized, being confined to developments that meet a specific industrial need. American Electroplaters Society, Radio Corp. of America, and others have recently published work on electroplating of antimonial alloys. Several chemical companies conduct continuous research on the properties and applications of the pigments, glasses, and glazes.

The Department of Agriculture has done research for the military aimed at developing a more useful fire retardant. U.S Naval Engineering Experimental Station has recently worked on improving antimonial-bronze bearing alloys.

The Bureau of Mines conducted research on the hydrometallurgy of antimony-bearing ores of the Coeur d'Alene district, Idaho, in an attempt to establish a more economical technique of recovering antimony from complex ores. Alaskan mercury-antimony ores were also studied by the Bureau of Mines to determine the technology and economics of separating the two principal ore constituents by fluidized-bed roasting of a bulk concentrate. In this process the mercury content is volatilized, and antimony is recovered from the residual calcine.

OUTLOOK

Antimony has a specialized consumption pattern which has not conformed to general economic patterns but rather to specific factors associated with storage batteries, textiles, plastics, and rubber. Expanding requirements in these applications are indicated to overbalance decline in some historical uses. The U.S.-required peacetime annual supply of antimony is therefore estimated to increase by some 2 percent annually to approximately 46,000 tons in 1970.

The geological and economic factors associated with the domestic antimony deposits precludes successful competition with peacetime imports and discourages hope for significant domestic output even under the incentives of an abnormally high price. Byproduct antimony is dependent on the market for the major valued constituents but the ratio of antimony to other metals is so small that only a moderate increase to 3,000 tons is forseen in the expanded production of associated metals.

Availability of antimonial scrap imposes a comparative inflexibility to secondary recovery of antimony in antimonial-lead. Improved lead price will bring out additional scrap but not on a sustained basis. Secondary supply of antimony is therefore believed relatively stable at 21,000 tons per year.

The 22,000 tons of primary antimony required in addition to domestic supply will be necessarily obtained as imports. Imports of ore to supply the domestic smelters and refiners of metal and oxide will be predominately from Mexico, Bolivia, and the Republic of South Africa with supplemental supply from Peru, Brazil, and Guatemala. Metal and oxide will be supplied principally by Yugoslavia, United Kingdom, Belgium-Luxembourg, Mexico, and Thailand.

PROBLEMS

The basic problem of the antimony industry is the assurance of an adequate supply to meet a rising world demand and, especially, to meet sharply fluctuating demand for new metal resulting from the wide difference in peacetime requirements and those of wartime. General geographic separation of the producing and consuming areas, lack of large, integrated mining establishments in most of the producing areas and dependence on the low-cost output of China has prevented a stable coordination of supply and demand.

Continuing depletion of high-grade ore in Mexico, Bolivia, and the Republic of South Africa is a problem necessitating adjustments in smelting practices and increase in production cost. This particularly affects the production of oxide directly from higher grade ores free of contaminating impurities.

The U.S. supply problem arises in part from the fact that presently known domestic antimony deposits are of small potential and uneconomical in competition with foreign production under normal market conditions. Thus the presence or potential of overwhelming foreign production availability is a deterrent to large scale exploration and development of domestic resources.

The consuming industry is faced with continuing problems in maintaining technological as well as economical advantages in applications of antimony in competition with other metals and organic synthetics.

The concentration of economically mineable antimony resources in a relatively few major areas of the world predicates continued dependence on these sources in an expanding industrial economy. Production and marketing policies of the centrally planned economics constituting the Sino-Soviet bloc will undoubtedly continue to be a disruptive factor in free world supply and, also, a deterrent to development of supplemental sources of supply. Depletion of easily mined, direct shipping ores of Bolivia, Mexico, and Republic of South Africa and the difficulties of development of additional sources to augment production predicates an increasingly tight supply and competition for available ores to meet international requirements for primary metal and oxide.

The price of antimony will reflect the rising cost of production and beneficiation of lower quality ores and market competition and is foreseen as unstable and substantially above that previously considered normal in peacetime.

ARSENIC

By Arnold M. Lansche [1]

ARSENIC TRIOXIDE or arsenious oxide (As_2O_3), is the most common compound of arsenic and in commerce is often called white arsenic. In the United States, white arsenic is produced principally as a byproduct of copper and lead smelting and in the recovery of other metals, notably gold and silver.

White arsenic is used principally for manufacturing calcium and lead arsenate insecticides. However, the usually unpredictable changes in insect infestation and the development of temporary immunities to insecticides among pests make the demand for arsenical insecticides unstable. This irregularity of demand is one of the basic problems of the arsenic industry. Other important uses of white arsenic are in wood preservatives, lead shot, glass, and weed control.

The use of arsenicals as insecticides has declined sharply since the advent of organic insecticides. The once popular lead and calcium arsenates have been largely replaced by organic compounds, such as dichlorodiphenyltrichloroethane (DDT), benzene hexachloride (BHC), toxaphene, and organic phosphate compounds, which have caused serious economic problems to manufacturers of arsenicals.

The United States is the world's second largest producer and largest consumer of white arsenic, producing about one-fourth and consuming nearly one-half of the world total.

The United States is in a favorable position to meet its white arsenic requirements. It is unlikely that any new uses for arsenic or its compounds will tax the existing resources or producing capacity of the Nation.

Research to develop the usefulness of arsenic has greatly increased, and several promising avenues have been opened which may lead to expanded use for both the metal and its compounds.

BACKGROUND

SIZE, ORGANIZATION, AND GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

Copper ores are the primary source of arsenic. Since 1926, Sweden and the United States have been the chief producers of white arsenic, with Sweden supplying about 23 percent of the total. In Sweden the compound has been produced by Boliden Mining Co., while the Anaconda Company at Anaconda, Mont., and American Smelting and Refining Company at Tacoma, Wash., produce white arsenic in the United States.

In 1963, 13 countries provided quantitative data on the production of white arsenic. Nine other countries are thought to have produced, but too little information was available to estimate production.

White arsenic is produced in five of the continents. Nations that produce the compound in North America are Canada, Mexico, and the United States. Brazil and Peru are the producing countries of South America; Argentina may produce some. In Europe the producers are Belgium, France, West Germany, Portugal, Spain, and Sweden; Greece and Italy did not report output in 1963; Austria, Czechoslovakia, East Germany, Finland, Hungary, and the United Kingdom may also produce some. Japan is the only reporting producer in Asia, but it is very likely that the U.S.S.R. and China produce white arsenic. Southern Rhodesia produces the compound in Africa.

DEFINITIONS OF TERMS, GRADES, AND SPECIFICATIONS

Prime white arsenic (As_2O_3) is a fine, white powder. Commercial specifications require that the refined product contain 99 percent or more

[1] Commodity specialist.

780-887 O—65——6

of arsenic trioxide; usually it contains 99.5 percent. It should be free from lumps, and for some uses a certain standard of solubility in nitric acid may be specified. Crude arsenic is grayish white, and sales contracts generally specify 95 to 98 percent arsenic trioxide. For sale to large consumers who buy in carlots, white arsenic is shipped in bulk and also packed in barrels containing 600 to 650 pounds each. For jobbing it is packed in casks of 100 pounds or more, and for the retail trade it is sold in packages of 1 to 10 pounds. Other important commercial compounds are arsenates or salts of arsenic acid. Both the arsenites and arsenates, except those of the alkali and alkaline-earth metals, are almost insoluble in water but are readily dissolved by acids.

TECHNOLOGY

Arsenic is not an abundant element. The average content of arsenic in the lithosphere compares with that of tin; however, it is widespread in occurrence. The arsenic concentration in sea water of 0.02 milligram per liter exceeds that of iron. The minerals realgar, orpiment, and arsenopyrite are more abundant. However, the most extensive mineralogical occurrence of arsenic is associated with copper, lead, cobalt, nickel, iron, and silver, either alone or with sulfur. The average arsenic content of igneous rock is reported to be 5 grams per ton (*11*).[2] Significant arsenic is found in the phosphate (mainly apatite) components of igneous rocks. Native arsenic occurs in some mineral veins. It is a general rule that arsenic begins to separate at the highest temperatures after the main stage of crystallization; that is, during the pegmatitic stage. Thus arsenic minerals are found in small quantities in deposits formed during the early and main stages of magmatic crystallization. In the late magmatic crystallites, arsenic is strongly concentrated in arsenopyrite (FeAsS), and loellingite ($FeAs_2$). Magmatic sulfides average about 2,000 grams of arsenic per ton. Pneumatolytic and hydrothermal deposits contain the greatest number of independent arsenic minerals.

Since most arsenic is produced as the oxide (white arsenic), a byproduct of the smelting of other metals, the metallurgy of arsenic is concerned chiefly with the treatment of arsenic-bearing flue dusts from smelting plants to recover the arsenic content as either crude or refined white arsenic. The crude flue dust, carrying as much as 30 percent arsenic trioxide, is mixed with a small quantity of pyrite or galena and roasted in a reverberatory furnace. The pyrite or galena prevents formation of an arsenite during roasting, producing a clinkering residue suitable for return to the process for recovery of other metals. The gases from the roasting furnace, containing the volatilized arsenious oxide, are cooled by passing them through a series of brick chambers or kitchens, in which the temperature ranges from 220° C. in the first chamber to 100° C. or less in the last. In this cooling process the arsenious oxide condenses as crude white arsenic and is collected in cooling flues, baghouses, or Cottrell precipitators. Much of the product is used in the crude form, but if a higher purity is required the operation is repeated to yield a product assaying 99 percent or more arsenic trioxide.

Metallic arsenic is prepared from white arsenic by reduction with charcoal. A 200- to 450-pound batch of white arsenic and charcoal is charged to a furnace where reduction takes place at about 1,200° to 1,300° F.

USES

White arsenic is the major ingredient in the United States in the manufacture of the arsenical insecticides, calcium arsenate and lead arsenate. The once popular paris green (copper acetoarsenite) insecticide is now of minor importance. Calcium arsenate is more effective than lead arsenate in combating the cotton boll weevil. Lead arsenate is used chiefly in poison sprays and dusts for destroying the coddling moth, plum curculio, cabbageworm, potato bug, tobacco hornworm, and pests that injure fruits and vegetables. Calcium arsenate and lead arsenate supply arsenic to agriculture in a form that will not injure plants but will destroy insects that eat plant leaves.

White arsenic alone or mixed with other substances is used as a wood preservative. Wolman salts (25 percent sodium arsenate) is a major wood preservative. Other wood preservatives include chemonite, and ammoniacal copper arsenite which has a composition prescribed by Federal Specification TT–W–549 to contain 1.84 percent cupric hydroxide $Cu(OH)_2$, 1.3 percent As_2O_3, 2.8 percent ammonia, 0.05 percent acetic acid and water. Greensalt is a chromated copper arsenate. There are three "Bolidensalts." "Bolidensalt" BIS is the trade name for zinc-chromium arsenate which has the approximate composition 20 percent arsenic acid H_3AsO_4, 19 percent mono-hydrogen sodium orthoarsenate $Na_2Cr_2O_7 \cdot 2H_2O$, 16 percent sodium dichromate, and 43 percent zinc sulphate, $ZnSO_4 \cdot 7H_2O$; the mixture is used in a water solution in wood preservative plants, and is applied to the wood under vacuum and pressure. The zinc and chromium arsenates are precipitated in the

[2] Italicized numbers in parentheses refer to items in the list of references at the end of this chapter.

wood fibers, making the treated wood resistant to leaching. The mixture of zinc and copper arsenates with sodium dichromate is trade-named "Bolidensalt" BIS Copperized and is used in the same way as "Bolidensalt" BIS. The copperized mixture has the following approximate composition: 20 percent H_3AsO_4, 19 percent Na_2HAsO_4, 16 percent $Na_2Cr_2O_7 \cdot 2H_2O$, 22 percent $ZnSO_4 \cdot 7H_2O$, and 22 percent copper sulfate, $CuSO_4 \cdot 5H_2O$. "Bolidensalt" K33 is the trade name for nonionic copper-chromium arsenate which has the following approximate composition: 34 percent arsenic pentaoxide, As_2O_5; 26.6 percent chromium trioxide, CrO_3; 14.8 percent cupric oxide, CuO; and 24.6 percent water. The nonionic arsenate is used to preserve wood in wooden cooling towers and other wooden structures subject to rot and in high-transmission-line poles because the electrical resistance of wood is increased. All ingredients in the nonionic arsenate are almost completely fixed in the wood, and no soluble by-products are formed. The arsenate is effective against all wood destroyers including soft-rot organisms. Another wood preserver, Osmosalts, is a mixture of 34 percent sodium fluoride, NaF; 25 percent sodium arsenate; 34 percent $Na_2Cr_2O_7$; and 7 percent dinitrophenol.

White arsenic is one of the most practical and persistent materials for permanent soil sterilization and has distinct advantages over soluble arsenic compounds used for this purpose.

Sodium arsenite is the active ingredient of herbicides used as weedkillers and to control aquatic plant life. It is used to some extent for sheep and cattle dips and for termite control.

The only extensive use of white arsenic not based on its poisonous quality is in glassmaking. A substantial quantity of the domestic output has been used as a decolorizer, as a constituent of opalescent and opal glass, and in enamels.

Probably the most familiar metallurgical application of arsenic is in manufacturing lead shot. Small additions of arsenic, up to 1 percent, change the surface tension of lead and permit the formation of spherical shot. Arsenic is used to improve particular properties of lead, copper, and some of their alloys. Additions of small amounts harden lead and minimize softening of lead-base-bearing alloys used in internal-combustion engines where elevated temperatures are encountered. Arsenical lead babbitts develop remarkably fine and uniform structure and have excellent fatigue strength.

An important metallurgical use of arsenic is in arsenical copper, where it increases corrosion and erosion resistance, raises the annealing temperature, and perhaps serves as a deoxidizer. Arsenical copper is useful in making automobile radiators and other manufactured objects assembled by soldering, because little or no strength is lost from soldering heats owing to the higher annealing (recrystallization) temperature.

Two leading commercial sulfides of arsenic are arsenic disulfide (As_2S_2), an orange-red compound found in nature as the mineral realgar but ordinarily made artificially, which contains 70 percent arsenic; and arsenic trisulfide (As_2S_3), a lemon-yellow material containing 61 percent arsenic and found in nature as orpiment or manufactured artificially. Realgar is used as a paint pigment, as a depilatory in tanning, and for making a white (Bengal) fire used in pyrotechnics. The red color is a desirable feature in treating hides or skins, but as sodium sulfide and calcium compounds are cheaper and nonpoisonous, they tend to displace arsenic sulfide for this use. Orpiment, or king's yellow, is used as a paint pigment and a reducing agent in chemical work. It is very bright yellow and has good covering power but is not permanent when exposed to light and cannot be mixed with many other colors. The pentasulfide (As_2S_5) has a more limited use in paint pigments, blue fire, and Bengal lights.

In medicine, arsenic sulfides and other arsenical compounds have been prescribed for centuries for many diseases, without true success. Fowler's solution, a 1-percent aqueous solution of potassium arsenite, introduced late in the 18th century, is considered to be the first really effective arsenical drug. It is dispensed today for certain human skin disorders and for animal therapy.

Gallium arsenide, gallium arsenide phosphide, indium arsenide, and indium-gallium arsenide have been used on a very small scale as diode components of masers and lasers which have a high efficiency in converting electric energy into infrared radiation.

BYPRODUCTS AND COPRODUCT RELATIONSHIPS

Arsenic occurs principally as a component of various metallic ores in which it is an undesirable impurity. The domestic output is obtained as a byproduct from the smelting or roasting of these ores for recovery of other metals, mainly gold, silver, copper, and lead. Often the arsenic content of the treated ores is very small. At many custom mills and smelters arsenic has been classed as a nuisance material.

ALTERNATE MATERIALS

DDT (dichlorodiphenyltrichloroethane) continues to be the most popular individual chlorinated hydrocarbon substitute for copper arsenate and lead arsenate. A group of chlorinated hydrocarbons, including aldrin, chlordane, dieldrin, endrin, heptachlor, and toxaphene, have grown rapidly in demand as substitutes for the arsenates; production of the arsenates was almost stationary in comparison. The organic phosphorus compounds malathion and parathion also were available as substitutes for the arsenates. About as much parathion as copper arsenate was produced in the period.

It has been claimed that most of the alternate materials have lower toxicities for humans than the inorganic arsenates; in October 1959, in the United Kingdom, the British Weed Control Council (*5*) recommended that manufacturers stop making arsenical sprays. However, in 1962, Carson (*3*) discussed at some length the toxicity of the arsenicals and suggested that the relatively new organic poisons are more deadly.

RESERVES

White arsenic reserves were estimated to be 2.5 million short tons in 1963. The wide occurrence of arsenic in ores of ferrous metals and nonferrous base metals implies that the arsenic supply is indefinite but directly related to output of metals in those two groups. Gold and silver ores are often associated with arsenic as arsenopyrite, orpiment, and realgar and contain large reserves of arsenic. The Getchell mine in Nevada began mining gold in June 1962, and the arsenic sulfide content was oxidized to white arsenic and sent to the arsenic waste ponds (*7*).

Data on foreign reserves were not available through 1963. It is unlikely that arsenic reserves in foreign countries will be available on a reliable basis in the near future because of the small demand.

SOURCES OF STATISTICAL INFORMATION

Production, sales, and stocks of white arsenic are voluntarily reported annually to the Bureau of Mines by domestic producers, but are withheld from publication to avoid disclosing individual company confidential information. Annual U.S. production of calcium and lead arsenates are obtained by the U.S. Department of Commerce, and similar information regarding the consumption of wood preservatives is obtained by the Forest Service, U.S. Department of Agriculture. White arsenic export data are not available. Imports of both white and metallic arsenic are available from records of the U.S. Department of Commerce.

PRODUCTION, CONSUMPTION, AND TRADE

Arsenic metal has not been produced in the United States since 1950. Production information about white arsenic in the United States has not been made public since 1959 because output has come from only two companies, The Anaconda Company at Anaconda, Mont., and American Smelting and Refining Company at Tacoma, Wash. In 1959 production of white arsenic was 5,189 short tons.

Mexico has been for many years the principal source of white arsenic imported by the United States. Mexico supplied 73 percent in 1963, France 14 percent, Sweden 12 percent, and Canada 1 percent. During 1959–63 white arsenic was occasionally received from the Netherlands, Poland-Danzig, Portugal, and the United Kingdom. There was 169 short tons of metallic arsenic imported for consumption in 1963.

Exports of white arsenic from the United States have not been reported by producers since 1947. Calcium arsenate and lead arsenate were exported in small quantities.

White arsenic, arsenic sulfide, and sheepdip are duty free. The duty on arsenic acid is 3 cents per pound. The duty on metallic arsenic was continued at 2.5 cents per pound when other rates were changed on August 31, 1963; paris green was removed from the free list, and the duty became 10.25 to 25 percent ad valorem; lead arsenate duty became 1.5 to 3 cents per pound; and compounds of arsenic not specified in the Tariff Act of 1930 were changed from a duty of 21.5 percent of their foreign market value to 10.5 to 25 percent ad valorem. The higher duties applied to Communist nations.

STRATEGIC CONSIDERATIONS

The production of white arsenic as a byproduct of copper and lead smelting has been so great that supply usually exceeds demand. The reserves of arsenic in the United States are adequate for all forseeable requirements. The output of white arsenic is entirely from Washington and Montana.

PRICES

Since February 9, 1961, the price of refined white arsenic has been stable at 4 cents per pound at New York docks (powdered, in barrels, carlots). The quotation for white arsenic,

f.o.b. Laredo, Tex. (the major port of entry), remained 4.5 cents per pound throughout 1958–60; on February 9, 1961, the price increased to 5.1 cents, where it remained throughout 1963. The bulk price of crude white arsenic was 2.6 cents per pound at both Laredo, Tex., and Tacoma, Wash. at the end of 1963; the barrel price at Tacoma was 4.2 cents per pound.

The Oil, Paint and Drug Reporter quoted the price per pound (carlots) of calcium arsenate from September 15, 1958, to October 3, 1960, at 9 to 9.24 cents; since then the price has not been quoted. Lead arsenate in 3-pound bags (carlots) declined from 27.5 cents per pound to 26.25 cents November 3, 1958, where it remained until March 30, 1959; on April 6 the quotation was 30.5 cents which held through January 22, 1962; on January 29 the quotation was 26 cents, at which it remained through 1962 and 1963.

There is no domestic price for arsenic metal.

TRANSPORTATION

White arsenic can be shipped in bulk (carlots) in covered hopper cars and in covered motor vehicles. Shipments are made in wooden barrels or kegs, or packed in portable, collapsible, rubber containers not over 70 cubic feet in capacity, as approved by the Bureau of Explosives. The rubber containers are authorized only for carload or truckload shipments. White arsenic can be imported in strong, siftproof, waterproof cloth containers, packed in metal-strapped wooden boxes. For jobbing white arsenic is packed in casks of 100 pounds, and for the retail trade it is sold in packages of 1 to 5 pounds.

Arsenic metal usually is shipped in lumps in sealed iron drums or kegs containing a maximum of 200 pounds.

Arsenic metal, white arsenic, arsenic acid, lead arsenate, calcium arsenate, and other arsenicals are classed as dangerous articles and must be packed, marked, certified, labeled, and described according to the Interstate Commerce Commission Code of Federal Regulations, title 49, part 71–90, section 72.5, for Class B Poisons, January 1, 1963 (Revised).

RESEARCH

As a result of research by industry, a method was patented for removing arsenic from complex ores of cobalt and nickel (*13*). Gallium arsenide single crystals have been grown on substrates of germanium, molybdenum, and tungsten (*1*, *12*). A diode was described for maser or laser operation (*8*). Tests were made by industry to evaluate cacodylic acid [$(CH_3)_2$-AsOOH] as a cotton plant defoliant and dessicater (*4*).

The Metallurgical Society of the American Institute of Mining, Metallurgical, and Petroleum Engineers published several papers which discussed the crystal growth, junction preparation, electrical, chemical, and optical properties of gallium arsenide phosphide and gallium arsenide (*2*, *6*, *9–10*, *14*).

OUTLOOK

The short-term outlook is for world production of white arsenic to continue at the 1959–63 level. The long-term outlook is one of steady supply closely tied to copper, lead, and zinc smelting, and to gold and silver production.

Research has brightened the prospects for greater consumption of arsenic in all of its old uses and has opened up new, small scale applications in maser and laser devices.

PROBLEMS

A basic problem of the arsenic industry is the highly fluctuating demand for arsenical insecticides, the principal market for white arsenic.

A marketing problem exists in the consumers' resistance to use of arsenical insecticides and weedkillers when other products are available.

Owing to its byproduct relationship to other metals, particulary copper and lead, production of white arsenic cannot be readily adjusted to highly fluctuating demand.

Lacking large-scale consumer markets, producers are frequently faced with the problems of disposal or augmenting storage facilities for a bulky and poisonous material.

ASBESTOS

By Timothy C. May [1]

ALTHOUGH asbestos has been known and used for at least 2,000 years, it was not until the end of the 17th century that it began to be regarded as something other than an object of superstition. It possesses some of the characteristics of the animal, vegetable, and mineral kingdoms. Although crude asbestos is naturally a dense mineral, it can be processed into a material as light, buoyant, and feathery as thistledown, which can be woven like cotton or wool.

Asbestos is a name applied to a group of naturally fibrous minerals. The largest producers of asbestos are Canada and the U.S.S.R. The United States is the largest consumer but produces only a small part of its requirements. The major part of the U.S. supply of chrysotile is imported from Canada. Most crocidolite and all amosite used in the United States are produced in the Republic of South Africa. Low-iron long-fiber chrysotile and amosite are important in defense purposes. Crocidolite has important industrial uses that are less directly related to defense problems. During World War II and several years thereafter, most grades of good quality asbestos were in short supply. The discovery of a large deposit of suitable low-iron chrysotile in British Columbia, Canada, relieved the short supply situation. The production and consumption of asbestos should continue to increase. The principal suppliers of U.S. markets—Canada and the Republic of South Africa—appear to have adequate reserves of asbestos to meet requirements for many years at current rates of consumption.

An important problem in asbestos is the complete dependence of the United States on foreign sources of supply. Other problems are the lack of a commercially satisfactory substitute for amosite, current lack of interchangeability of the various types of asbestos, waste disposal, and biological effects of asbestos upon the industrial employee.

BACKGROUND

SIZE, ORGANIZATION, AND GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

The United States leads in manufacturing asbestos products and consumes 23 percent of the world asbestos production; however, domestic sources furnish only 9 percent of the raw asbestos needed. Most of the supply is obtained in Canada, but important quantities, particularly of special kinds and grades, originate in the Republic of South Africa (*4–5*).[2]

The Province of Quebec, Canada, has the largest mines and mills in the world. The U.S.S.R. rivals Canada as an important producer. The Republic of South Africa, Southern Rhodesia, Swaziland, Italy, and the United States are substantial producers, and smaller supplies originate in many countries. The variety chrysotile constitutes about 95 percent of the world supply, and unless otherwise designated the data herein relate to chrysotile.

Total world production in 1963 was 3.2 million short tons of all grades and varieties. Of this total, Canada produced about 40 percent, the U.S.S.R. 38 percent (estimated), the Republic of South Africa 6 percent, Southern Rhodesia 4 percent, the United States 2 percent, Italy 2 percent, and Swaziland 1 percent.

Prior to 1962, the only large production of asbestos in the United States was from a deposit in Eden and Lowell Townships, Vt., in what is regarded as a southern extension of the

[1] Commodity specialist.
[2] Italicized numbers in parentheses refer to items in the list of references at the end of this chapter.

Quebec deposits. In 1963, deposits in the Copperopolis, Coalinga, and Napa areas in California began production, and in the next few years their combined production is expected to exceed that of Vermont. Several operators have small chrysotile mines in an area about 60 miles long and 25 miles wide in the Salt River and Cherry Creek basins of Gila County, north of Globe, Ariz. These are the only sources of chrysotile asbestos that have been developed in the United States. Chrysotile deposits are known in Montana, Wyoming, and other States, but production has been negligible. In addition, amphibole asbestos is produced sporadically in North Carolina and Georgia (*6–8, 16, 20–21, 25–27*).

The largest known asbestos deposits in the free world are in an area 75 miles long by 5 or 6 miles wide between Danville and the Chaudière River Valley, in the Province of Quebec, Canada. Eight companies are actively engaged in mining in this area. Six of these are subsidiaries of companies that operate large asbestos-products plants in the United States. Deposits occur elsewhere in Canada. Asbestos was mined in Munro Township, 12 miles east of Matheson, Ontario, from 1950 until the mine closed down on July 31, 1964. Asbestos has been mined continuously in northern British Columbia since 1953. In mid-1963 a new mine began operating at Baie Verte in Newfoundland. An important deposit in the northern Ungava region of Quebec is being examined and may be considered a prospective producer. Canadian production in 1963 was valued at Can-$135 million, whereas U.S. production had a sales value of about $5 million.

The Soviet deposits, situated in the Bajenova district of the Urals, are extensive. The mines and mills are large, and most of the fiber is used within the country in the manufacture of various asbestos products.

Southern Rhodesia is an important producer of chrysotile asbestos, particularly in the Shabani area. The fiber from these deposits has such a low iron content that it can be made into the excellent electrical insulating material that is required in the construction of electric cables for use on shipboard. Most of the other deposits of the world, except the comparatively small ones in Arizona and the recently discovered large one in British Columbia, have a substantially higher iron content, making them unsuitable for electrical insulation. Swaziland and the Republic of South Africa also produce chrysotile in substantial quantities. The Republic of South Africa produces two special types of asbestos—amosite, found commercially nowhere else, and crocidolite (blue asbestos), produced also in Australia and Bolivia. Most of the African production is exported (*24*).

Smaller operations are in Cyprus, Italy, Finland, France, Australia, Bolivia, Brazil, Japan, and several other countries.

DEFINITION OF TERMS, GRADES, AND SPECIFICATIONS

Asbestos is a name applied to a group of naturally fibrous minerals. The principal variety is *chrysotile*, a hydrous magnesium silicate having the theoretical formula $3MgO \cdot 2SiO_2 \cdot 2H_2O$. Other commercial varieties are *amosite*, a complex iron-magnesium silicate, $(FeMg)SiO_3 \cdot 1$–5 pct. H_2O; and *crocidolite*, a sodium-iron hydrous silicate, $NaFe(SiO_3)_2 \cdot FeSiO_3 \cdot H_2O$. Of minor importance are *tremolite*, $Ca_2Mg_5Si_8O_{22}(OH)_2$, and *anthophyllite*, $(MgFe)_7Si_8O_{22}(OH)_2$ (*3*)

Chrysotile, the principal variety of commerce, is graded according to fiber length. Fibers three-eighths of an inch long or longer are classed as the spinning grades suitable for use in making fabrics. According to the Canadian classification, the crudes (hand-cobbed long fibers) and spinning fibers comprise groups 1, 2, and 3. The succeeding groups are of progressively shorter fibers. Group 4 is designated as shingle stock; group 5, paper stock; group 6, waste stucco and plaster; and group 7, refuse or shorts. Most of these groups are divided into several subgroups. Such groupings comprise the commercial specifications. The consumer designates the grade desired, such as 3R or 4K. Grades may be blended to satisfy special needs. For some uses the chemical composition is important. Thus, for electric insulation an upper limit for the iron content may be specified. The methods of classification used in the principal producing countries are discussed in detail in a Bureau of Mines publication (*4*).

TECHNOLOGY

Most chrysotile asbestos deposits, including those of Vermont and California in the United States, Canada, Southern Rhodesia, Swaziland, the Republic of South Africa, and the U.S.S.R, consist of irregular cross-fiber veins (closely packed fiber set at a right angle to the faces of the rock fractures) or slip-fiber zones (shear planes in rock filled with fiber matted together parallel to the seam) in massive serpentine. Such deposits commonly extend to unknown depths. Those of Arizona, however, consist of more or less horizontal asbestos-bearing serpentine zones in thin-bedded limestone. Such deposits are generally less extensive and less persistent than those in massive serpentine. The amosite and crocidolite of the Republic of South Africa occur in banded ironstones that

are so folded and contorted that the veins are very irregular (*16*, *24–27*).

In Vermont, the fiber-bearing rock is removed from an open pit, which is worked on three 125-foot-high benches. Similar methods are employed in the Copperopolis district in California; but in the Coalinga district the highly sheared ore is simply "plowed" and allowed to air-dry, and the coarse fraction is screened out from the millfeed. The usual practice in Arizona is to drive a 5- to 6-foot heading in barren limestone beneath the fiber zone, which is later blasted down and hand-cobbed. The Canadian mines were originally open pits, but there has been a gradual transition to underground mines using block-caving methods. The chrysotile of Southern Rhodesia, the Republic of South Africa, and Swaziland is obtained from underground mines. Amosite is obtained chiefly from large underground workings, and blue asbestos from small open pits and shallow mines. The Soviet deposits are worked both in open pits and underground. Cyprus has large open-pit workings (*5*, *17*, *21*, *24*).

Asbestos milling is a complex operation involving primarily the separation of fiber from rock and classification of the fiber by length. Asbestos, unlike the metals, is not a single commodity, but comprises a series of grades depending upon the length of individual fibers. The operator has little control over the proportions of the various grades, as they are fixed in nature, but he has the important task of minimizing fiber damage. He must mill the rock with as little fiber breakage as possible, because short fibers are worth much less than long ones. Special types of rock disintegrators have been developed, and reduction is accomplished in stages with fiber removal by air suction at each stage (*14*).

In Arizona the hand-cobbed rock is reduced in jaw crushers and the fiber separated by screening. Fiber which remains on a ½-inch screen is classed as No. 1; that which passes a ½-inch mesh and remains on a ¼-inch mesh, No. 2; through ¼-inch mesh and on ⅛-inch mesh, No. 3; and that which passes through the ⅛-inch mesh, No. 4. Nos. 1 and 2 are classed as spinning grade if the fibers are not too harsh. Some spinning fiber is obtainable from No. 3.

Special milling techniques have been developed for the matted short fiber chrysotile of the Coalinga district of California, including grinding and wet-milling processes.

In Vermont and Canada the mills are large and complex. The fiber is classified in many grades, such as spinning, cement stock, and paper stock.

USES

The uses of asbestos fibers of all varieties are numerous and range from floor tile to rockets. The longer fibers—Canadian groups 1, 2, and 3, and their equivalents from other countries—are used for making textile products such as cloth, yarn, tape, and rovings. The asbestos is spun and woven in much the same way as cotton, silk, or wool. Asbestos fabrics are used extensively for lagging cloth, brakeband linings, clutch facings, safety clothing, packings, gaskets, and various other appliances. Low-iron fiber is used in cable insulation (*2*, *13*).

Shorter fibers such as Canadian group 4, and to some extent 5 and 6, are used widely for asbestos-cement products such as roofing shingles and flat and corrugated siding. These products consist of about 80 percent portland cement and 20 percent asbestos. Canadian groups 4 and 5 and African amosite are used extensively for making 85 percent magnesia block and pipe insulation. They consist of about 85 percent basic magnesium carbonate and 15 percent asbestos. Canadian group 5 is suitable for asbestos paper and millboard manufacture. Such products are made on standard papermaking machines. An important use of asbestos paper is for making the so-called air-cell pipe covering. The shortest fibers are used for boiler and roofing cements and as filler in asphalt floor tile and various other products.

Amosite is used for felted insulation in blanket form for high-temperature service up to 900° F. A loosely compacted form is applied as a covering for marine turbines, jet engines, and similar applications. Amosite is also used as a constituent of 85 percent magnesia insulation and lightweight, fire-resistant marine partition board.

Long-fiber crocidolite (blue asbestos) is woven into fabrics used for locomotive boiler lagging (in Great Britain) and for acid-resistant packings and gaskets. The principal use of the shorter crocidolite fibers is in making asbestos-cement pipe. Bolivian crocidolite has been found useful for making gas-mask filters.

Tremolite and anthophyllite are used for chemical-resistant filters, as welding-rod coating, and as fillers in various products.

BYPRODUCTS

There are virtually no commercial byproducts at asbestos mines and mills. The fiber comprises a small part ranging commonly from 5 to 7 percent of the rock mined, and the waste rock consists of pulverized serpentine for which very little commercial use has been found. In

Vermont, however, an appreciable amount is used for road metal. The possibility of recovering magnesia from it has been proposed, but no practical method has been developed.

ALTERNATE MATERIALS

Fiberglass is used as a substitute for asbestos in some applications, chiefly in the field of heat insulation. Fabrics woven with a plied yarn having one strand each of glass and asbestos yarn are advantageous for some uses where light weight and high strength are needed. Glass filaments in submicron sizes made by highly refined processes involving the use of platinum dies are technically satisfactory substitutes for amosite in blanket insulation, but the cost is five or six times as great as that of amosite. Fiberglass is not a satisfactory substitute for asbestos in friction materials or asbestos-cement products.

Silicone products, organic compounds, and plastics are used as substitutes in certain limited applications. The use of calcium silicate, diatomite, and magnesia in some instances reduces asbestos requirements in end products.

Aluminum sheets are being used as a partial substitute for asbestos where insulation against radiant heat is required.

Synthetic asbestos has not yet been made commercially. Its current status is covered later in the section devoted to research. New types of heat-resistant plastics are being substituted for chrysotile in some forms of electrical insulation. Substantial progress has been made in substitution of Novabestos and Quinterra papers for electrical insulation. There is, however, no satisfactory complete substitute for strategic grades of chrysotile in some forms of dielectric insulation.

Fibrous glass and chrysotile asbestos are substitutes for amosite, but they are not as resistant to steam, seawater, and alkalies under all working conditions. For 85 percent magnesia and calcium silicate insulation, textile grades of chrysotile may be substituted for amosite.

Experimentation on materials that may be substituted for asbestos indicate that fiberglass can replace asbestos for some types of heat-insulating products. Cloth of good quality is made using alternate strands of fiberglass and asbestos yarn. Such substitution extends the supply of spinning-grade asbestos. Fiberglass cannot be used successfully in friction materials such as brake band linings, nor in some of the highly specialized electrical insulation uses. Recent advances in the manufacture of glass fibers offer opportunities for wider substitution. Organic plastics and silicone products have limited substitute applications.

RESERVES

In Vermont, a reserve of at least 1 million tons of chrysotile fiber appears to be assured. A small proportion of this quantity is of spinning grade. In California, measured and indicated reserves totaling more than 1 million tons are reported for the Copperopolis area; these reserves consist chiefly of types and grades similar to those in Quebec, Canada. Reserves of several hundred million tons of rock that will yield matted short-fiber chrysotile asbestos are reported for the Coalinga area in California (*20*). The Arizona reserve is difficult to estimate but is probably small.

The world appears to have an adequate asbestos reserve for at least 25 to 30 years at current or moderately enlarged rates of output. The chief suppliers of U.S. markets—Canada and the Republic of South Africa—appear to have adequate reserves for long-range planning. It is difficult to calculate South African reserves owing to the intensive folding encountered in nearly all the asbestos areas. The duplication of the asbestos bands through folding has resulted in large reserves (*18*). The U.S.S.R. reserve is probably large enough to supply its domestic economy for many years.

SOURCES OF STATISTICAL INFORMATION

Annual data on the production and shipments are obtained from domestic producers and consumption of strategic grades are reported by consumers to the Bureau of Mines.

World production and trade data also are compiled by the Bureau of Mines, and U.S. imports and exports are obtained from the U.S. Department of Commerce.

The Bureau of Mines publishes the principal statistics annually in the "Asbestos" chapter in the Minerals Yearbook.

PRODUCTION, CONSUMPTION, AND TRADE

World production of asbestos by country of origin is given in table 1. Most of the asbestos production is chrysotile asbestos, but 160,000 to 200,000 tons of the world's production each year consists of amosite and crocidolite. Table 2 shows the production of these two varieties of asbestos by country of origin.

The United States is the largest consumer of asbestos in the world. Table 3 shows U.S. asbestos consumption and imports from 1954 to 1963. Table 4 shows imports of special grades of asbestos.

From 1949 to 1953 the United States consumed on an average about 50 percent of the total world production. Domestic consumption more than doubled from 1945 to 1951, but thereafter it remained fairly constant, except for 1955, while world production continued to increase. In 1963 the United States consumed about 23 percent of the total world production.

Domestic sources furnish only a small percentage of U.S. asbestos requirements. Arizona, the only present natural source of low-iron chrysotile in the United States, has rarely produced more than 600 tons per year of the spinning grades, and the output usually has been considerably lower than that figure. A large part of the production of crudes No. 1, No. 2, and No. 3 since 1953 was purchased by the U.S. Government for stockpiling. The purchase program terminated at the end of 1962.

Vermont and the Copperopolis district of California are the only consistent U.S. producers of Quebec-type asbestos. Both are predominantly producers of short fiber, but the Vermont asbestos mines produce about 500 to 700 tons per year of spinning length fiber. Most of it is applied to nonspinning uses.

On a tonnage basis Canada furnished 90 percent of the U.S. imports (1959–63), but most of this material (97 percent) was of the shorter grades. The comparatively small quantities received from Africa are more important than would appear on a tonnage basis, because they consist largely of special kinds and qualities unobtainable elsewhere. Under emergency conditions imports of spinning fibers are of primary importance. Imports of spinning fibers from Canada average about 17,000 tons per year. The longer fibers of chrysotile suitable for spinning purposes represent a small fraction of the total production. Shortages of spinning-grade fibers have previously occurred.

The spinning grades of asbestos produced in Southern Rhodesia were of great importance during World War II and the early postwar years, because they constituted the principal source of low-iron chrysotile suitable for shipboard electric-cable construction. Production began from the new source of supply of low-iron chrysotile in northern British Columbia in 1953, and in 1962 over 5,000 tons of spinning fibers was imported from that source.

Production of amosite in the Republic of South Africa has increased from an average of 20,000 tons per year during the 1940's to 78,000 tons in 1963.

Imports of amosite into the United States from 1959 to 1963 averaged about 19,000 tons per year. Part of the imported material has been placed in the national stockpile; hence industrial consumption has been somewhat lower than the aforementioned figures. Probably

TABLE 1.—*World production of asbestos, unmanufactured, by principal countries*

[Thousand short tons]

Country	1954–58 (average)	1959	1960	1961	1962	1963

Amosite	14	17	20	15	20	22
Crocidolite	20	18	20	18	17	11

larger quantities would have been used had they been obtainable, because there has been and still is a stringency of supply.

Most crocidolite originates in the Republic of South Africa, but substantial tonnages are received from Australia and small quantities from Bolivia. The commercial demand for Bolivian blue is very small. African production of crocidolite has increased from an annual average of 10,000 tons during the 1940's to almost 100,000 tons in 1963. Imports of crocidolite advanced from 12,000 tons in 1954 to 18,000 tons in 1959 and dropped to 11,000 tons in 1963.

About 10,000 tons of unmanufactured asbestos was exported from the United States in 1963. The exports consist chiefly of Canadian fibers blended and prepared in various ways to suit the needs of Latin American and European buyers.

Unmanufactured asbestos enters the United States duty free.

STRATEGIC CONSIDERATIONS

Asbestos kinds and grades of greatest strategic importance are being stockpiled. The national stockpile items are spinning-grade chrysotile and amosite. Bolivian blue crocidolite is no longer considered strategic. On June 30, 1964, the maximum stockpile objective for chrysotile was 13,700 short tons. Government inventories totaled 9,287 tons, of which 6,224 was in the national (strategic) stockpile, 724 in Commodity Credit Corp. (CCC) stocks, and 2,339 tons in the supplemental stockpile. The stockpile objective for amosite was 40,000 short tons, and inventories totaled 65,838 tons, of which 11,705 was in the national (strategic) stockpile, 23,196 in CCC stocks, and 30,937 in the supplemental stockpile.

The United States is dependent upon foreign sources for 90 to 93 percent of its requirements for all grades of asbestos. The principal source of low-iron spinning grade chrysotile asbestos is British Columbia, Canada. The former chief source was Southern Rhodesia, from which our essential needs were supplied until the end of the Korean war. A small amount of low-iron long-fiber chrysotile is available from Arizona. The only source of commercial grades and quantities of amosite is a limited area in Transvaal, Republic of South Africa. The United States is also completely dependent on foreign sources for crocidolite.

GOVERNMENT PROGRAMS

During World War II controls were in effect to restrict exports of asbestos needed in the military program. These controls were removed by executive order on September 10, 1945. During the Korean war the supply situation again became acute, and in 1950 and 1951 controls were invoked that required licenses for export of all grades of asbestos. The license requirement was removed for the nonspinning grades in 1953, and for the spinning fibers in 1954; however, export licenses are required for shipments to Communist nations.

The allocation of asbestos supplies effected during World War II has been deemed unnecessary since the Korean war, but the National Production Authority (NPA) issued an order (M–96 dated January 17, 1952) that gave priority to military and essential civilian uses of the limited supply of spinning grades of chrysotile asbestos. It prohibited the use of certain grades of spinning fiber for other than certain specified end uses. As supplies of spinning-grade chrysotile had become adequate for all commercial and military needs early in 1953, order M–96 was revoked by the NPA May 12, 1953.

The discovery and development of new asbestos deposits have always been a most urgent necessity. To assist in discoveries the Office of Minerals Exploration (OME), and the Defense Minerals Exploration Administration which was abolished in 1958 and whose functions were assumed by OME approved 19 asbestos exploration contracts as of December 1963. Only five contracts led to certification of discovery and none of these were significant to the overall supply situation.

A government depot in Globe, Ariz., was opened for the purchase of domestically produced asbestos meeting certain specifications. Under Public Law 733 (1956), a government purchase program at premium prices for domestic low-iron chrysotile asbestos was established which was terminated on December 31, 1958. In 1959 the stockpile objectives for low-iron chrysotile were raised, and a barter program was established to acquire the additional fiber needed through exchange of agricultural surpluses. The U.S. Department of the Interior recommended purchase of 500 tons of low-iron chrysotile from domestic mines to assist the domestic industry and to establish a domestic mobilization base for production.

Amosite and chrysotile have been acquired for the stockpile by purchase and barter, and crocidolite has been acquired by barter.

PRICES

Although asbestos has had an erratic price history, prices during the past 5 years have remained relatively stable. Quebec chrysotile fiber prices in 1963, f.o.b. mine, ranged from Can$40 per short ton for 7T, which is the short-

est of the regular fiber grades generally produced, to Can$875 for the longest of the milled fibers. Crude No. 1 sold for Can$1,410 or more per ton. British Columbia fibers sold from Can$142 for AX to Can$1,522 per ton for crude No. 1.

Vermont chrysotile is produced in grades similar to those of Canada and ranged in price in 1963 from $40 for group 7 to $402 for group 3, f.o.b. mine. Arizona fibers ranged in price from $58 for group 7 to $1,650 for crude 1, f.o.b. Globe, Ariz. (*1*).

As sales of African and Australian asbestos are negotiated separately, market quotations are not available.

TAXES

There are no special taxes on the asbestos industry. Producers are granted a depletion allowance of 23 percent on domestic production and 10 percent on foreign production.

TRANSPORTATION

The Quebec and Vermont deposits are within easy rail haul to most of the plants manufacturing asbestos products in the industrial areas of the Eastern United States. The African deposits are remote from the principal markets and have high transportation expenses. Transportation from British Columbia is difficult and costly, but a shorter route is in prospect. The Arizona miners have difficult transportation problems. The mines are in the vicinity of Globe, the nearest railhead, at distances ranging from a few miles to 104 miles, with an average haul to the railroad of about 50 miles. The major consumption centers are in the Northeastern United States, and are much closer to Quebec, Canada, than to Arizona. Consumption of asbestos is growing along the west coast of the United States. Comparable growth of the industry has taken place in other areas where fiber from California would be competitive, in terms of freight rates, with that from Quebec.

RESEARCH

Research on production has been conducted by companies operating mines in Canada. Substantial research has been conducted on utilization of the more plentiful shorter grades in applications where longer grades are preferred. For instance, it has been found that more complete fiberization, permitting better contact of cement and fiber, will allow groups 5 and 6 to be blended in increasing proportions with group 4 in making asbestos-cement products.

Two companies have developed processes for reducing the iron content of Quebec asbestos to make it suitable for electrical uses. The Johns-Manville Corp. manufactures Quinterra paper from such fibers. Raybestos-Manhattan, Inc., has developed a process for making a low-iron product known as Novabestos. Both Quinterra and Novabestos papers may be interlaminated with a fiberglass fabric or grid to give additional strength. These products are now manufactured commercially and are used extensively in cable construction and for other nonferrous applications.

The Cape Asbestos Company Ltd., London, has investigated tensile testing of crocidolite and amosite, their chemical resistance, and their behavior in solutions of various chemicals and surface active agents. The only laboratory in the world devoted entirely to fundamental research on asbestos fibers was recently constructed by Turner and Newall Ltd., Manchester, England. New types of equipment were developed to sort asbestos fibers according to diameter and length (*19*).

In this country, the Naval Research Laboratory has conducted experimental work on the possible use of a papermaker's Vortrap to remove iron minerals from Canadian chrysotile. The Bureau of Mines conducted similar experimental work with its own equipment. The tests indicated that the magnetic iron content of ordinary Quebec asbestos can be reduced to satisfy the requirements of 2 percent or less stipulated in the national stockpile specification for nonferrous chrysotile.

The Naval Research Laboratory has developed a fiberglass gas mask filter said to be superior to those made of Bolivian blue asbestos. Bolivian crocidolite is, therefore, no longer regarded as essential.

Much work has been done on the synthesis of asbestos, but limited progress has been made. The Bureau has synthesized amphibole asbestos, but the fibers made are weak and brittle. The Bureau also has synthesized asbestiform compounds not found in nature that have some of the properties of asbestos. Chrysotile, the type of asbestos most in demand, is difficult to synthesize. Fibers of submicroscopic length only have been made (*9–12*, *15*, *22–23*). The Bureau has performed core drill tests on various properties to determine the occurrence of asbestos, and the Geological Survey has studied the geology of asbestos deposits in various parts of the country (*6–8*, *16*, *25–27*).

OUTLOOK

The trends in the consumption of asbestos will follow those of industrial production and building construction. Asbestos will continue to find wide industrial use in friction materials, pipe insulation, packings, gaskets, plastics, and many other products. Also, large quantities of asbestos will be used for asbestos-cement pipe, roofing and siding products, floor tile, insulation, moulding compounds, and millboards. The demand in the United States for all types and grades of asbestos should increase 3 to 5 percent annually. Annual consumption of asbestos should reach 900,000 tons in 1965–70, and may exceed 1 million tons by 1975 in the absence of an industrial recession. Domestic production should increase annually and attain 95,000 tons per year during 1965–70; consequently, domestic mines will supply 10 percent of the Nation's overall requirements. Most of the supply, however, will consist of nonspinning, low-unit-value fiber.

As new markets come into being and old markets grow, world production of asbestos fibers will rise. As worldwide demand for asbestos increases, there is much interest in exploring new areas. New occurrences in Ireland, Australia, and Mexico have been examined. Additional mills in Quebec, and others in prospect, assure rising availability of supplies. Newly discovered deposits undergoing exploration and development, in northern Newfoundland, Quebec, Ontario, and British Columbia, promise further expansion and output. Expansions have also taken place in the U.S.S.R., Southern Rhodesia, and the Republic of South Africa where all types of asbestos are produced. Utilization of short-fiber grades is growing throughout the world. Deposits rich in short-fiber chrysotile, being developed in California, will add substantially to domestic production as markets are found. No spinning-grade fiber is expected from these deposits. Imports are expected to increase from Canada, Southern Rhodesia, and the Republic of South Africa. Supplies of asbestos apparently will be adequate for both short-term (5-year) and long-term (10-year) requirements. World production has doubled over the past 10 years to the present 3.2 million tons. World demand is expected to require world output of 4 to 5 million tons within the next decade.

U.S. requirements for low-iron chrysotile of spinning-grade quality have been greatly reduced because of the decline in military usage and the substitution of other electrical insulation materials, such as fibrous glass, plastics, and silicone rubber. Some Quebec fibers are now processed in such a manner that their iron content is reduced sufficiently to make them suitable for some electrical insulation. However, the United States still needs about 2,500 tons per year of low-iron fiber. Beneficiated chrysotile imported from Quebec is being used in the manufacture of low-iron fibers. Imports of low-iron chrysotile from British Columbia will be adequate to meet special needs and provide a surplus for general-purpose uses. Low-iron tapes and papers using beneficiated chrysotile imported from Quebec are suitable for some electrical insulation, thereby relieving part of the demand for low-iron fibers. Arizona mines will remain a small factor in industrial supply.

High-iron spinning-grade chrysotile requirements for the short-term are estimated at almost 20,000 tons per year, increasing over a 10-year period to 25,000 tons. Most of the supply comes from Canada, with small amounts produced in Vermont and imported from Africa and other overseas sources. Information from the Canadian Department of Mines and Technical Surveys indicate that Canadian production of spinning grades is about 30,000 tons per year. The industry could produce about double this quanitity if the market so required. Approximately 50 percent of the supply is currently exported to the United States. From this it appears that Canada is an adequate source for all foreseeable requirements.

Amosite requirements of the United States are increasing steadily. Imports reached nearly 22,000 tons in 1963 and will probably increase to 30,000 tons per year within the next 10 years. Mining and milling facilities are being expanded in the Republic of South Africa and are expected to remain above the short-term and long-term requirements. Amosite is particularly suitable for use in heat-insulating materials.

Crocidolite requirements have increased substantially during the past 5 years. The long-fiber grades are in relatively small demand, but use of the shorter fibers in asbestos-cement pipe manufacture is increasing rapidly. With expanding facilities for pipe manufacture in the United States, demand for crocidolite may reach 30,000 tons per year within 10 years. Large deposits of crocidolite are known only in the Republic of South Africa and Australia. African production facilities are being expanded as new fiber-bearing zones are discovered and developed. Production of crocidolite in Australia increased 30 percent during 1958–62. Reserves are said to be extensive.

The outlook for successful synthesis of commercial asbestos remains uncertain.

PROBLEMS

The complete dependence of the United States on foreign sources for some types of asbestos is an important problem that concerns the national economy and defense needs. Export duties and other controls by producing countries could increase costs to U.S. consumers.

The disposal of surplus inventories of asbestos in the Government stockpiles is of concern to the producing industry. The absence of any clearly defined and predictable long-term disposal program has heightened this concern.

More data are needed on the fundamental characteristics of asbestos to serve both as a foundation for future research on synthesis and as a guide to new and improved usage of all varieties of fiber.

Information is needed on the interchangeability of the many types of asbestos in manufactured products. Development of substitutes for scarce types and grades or asbestos fiber is a difficult problem because of the superiority of asbestos to other materials for special use.

The biological effects of asbestos are a serious health problem in the industry. The hazards are recognized, however, and adequate filtering and ventilation are provided in processing plants. The extensive use of asbestos in a variety of industrial applications has drawn attention to the medical problems associated with this use. These problems include pulmonary asbestosis and neoplasia associated with occupational exposure to asbestos.

Other problems include occasional shortages of spinning-grade fiber, utilization of waste from asbestos plants, and the development of potential large-scale uses for the widespread resources of actinolite, anthophyllite, and tremolite varieties that are in little demand.

BARIUM

By Richard W. Lewis [1]

TWO barium minerals, barite ($BaSO_4$) and witherite ($BaCO_3$) serve a wide variety of markets. Chemical inertness, high density and low cost make barite especially suitable for well-drilling muds, which is by far its greatest use. Witherite is of minor commercial importance to the barium chemical industry. Furthermore world supplies of witherite are quite limited whereas ample barite reserves are dispersed throughout the world.

Domestic production of barite totaled 803,000 short tons in 1963. There was no domestic production of witherite, the other commercial barium mineral, in 1963, but some was imported. Twelve States reported production of barite in 1963. Arkansas and Missouri—the leading barite-producing States—along with Georgia and Nevada accounted for 92 percent of the total. Barite is mined by both open-pit and underground methods and at some operations is concentrated by flotation.

Consumption remained at about the same level from 1958 through 1963 except that in 1959 it was about 200,000 tons higher owing to increased demand for oil-drilling mud. No appreciable change from this is expected during the next 4 or 5 years.

Domestic measured and indicated reserves of barite are estimated to total about 46 million tons; the largest reserves are in Missouri, Arkansas, Nevada, and California. The inferred barite reserve is estimated at 67 million tons.

The problems of heavy dependence on a single market, of locating additional deposits near major consuming areas, and of maintaining a satisfactory reserve position are of long-range importance to the industry. Research is needed on methods of exploring for new deposits and on the recovery of barite from complex ores and waste products. In addition, research on the properties of barium compounds and for new uses is required.

BACKGROUND

The domestic barite industry dates back to the middle of the 19th century when, in 1845, production of barite was first reported in Fauquier County, Va. About 5 years later, production was begun in Missouri. In 1880 Tennessee became the third barite-producing State; and 1901 and 1903 saw Georgia and Kentucky, respectively, become producers. California came into production in 1914, and in 1941 the deposit of barite at Malvern, Ark., was opened when Magnet Cove Barium Corp. successfully separated barite from associated minerals by flotation. The first washers and jigs used in the industry were installed in Georgia and Tennessee in 1914–16 and in Missouri in 1923–24.

Barite's first use was as a filler in white paints; however, in 1892, with the advent of the domestic lithopone industry, a second important market was opened. In 1908 Chicago Copper Refining Co. (now Chicago Copper & Chemical Co.) began manufacturing barium chemicals at Blue Island, Ill. A fourth market for barite came into existence in 1926 when a patent was obtained on the use of barite as a weighting agent in rotary drilling muds. This today is the largest use of barite.

SIZE, ORGANIZATION, AND GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

The two principal producers of barite in the United States are Baroid Sales Division, National Lead Co., and Magnet Cove Barium Corp., a subsidiary of Dresser Industries. In addition several firms produce 40,000 to 100,000 tons annually, and numerous smaller firms produce less than 40,000 tons annually. The

[1] Commodity specialist.

780–887 O—65——7

smaller firms usually sell their production to the large producers or to custom grinders. A total of 41 firms produced crude barite in 1963.

There were 13 producers of barium chemicals and 2 producers of lithopone in 1963. Of these, only one firm owns its source of raw material.

The two leading barite-producing States are Arkansas and Missouri; Georgia and Nevada are also major producing States, while California, Idaho, Kentucky, New Mexico, Montana, South Carolina, Tennessee, and Texas recorded minor production in 1963. Occasionally output has been reported from Arizona, Utah, and Washington.

Most of the barite produced in California and Nevada is consumed by oil and gas well drillers and the barium chemical industry in California. Output from Montana and Idaho is used in oil exploration in those and nearby States, and some is exported to Canada. Virtually all of the Arkansas and most of the Missouri production goes to midcontinent and gulf coast well drillers. The remainder of Missouri's production is consumed by the paint, glass, and chemical industries in the Midwestern and Eastern States. Oil well drillers in Texas and Louisiana are supplied partially from Southeastern production and from Texas with the remainder imported.

Barite occurrences have been recorded on every continent and in every major country. Some domestic producers have interests in deposits in Brazil, Greece, Mexico, and Canada.

Some of the more important barite-producing countries other than the United States are Canada, West Germany, Italy, Mexico, Morocco, the U.S.S.R., and Yugoslavia. Output has been reported from at least 35 countries.

The only commercial production of witherite is in Northumberland, England, from where it is exported to consuming countries. Some witherite was produced prior to 1948 in Mariposa County, Calif.

DEFINITION OF TERMS, GRADES, AND SPECIFICATIONS

Two minerals are commercial sources of barium and barium compounds. They are *barite* ($BaSO_4$), the principal mineral of commerce, and witherite ($BaCO_3$). Barite theoretically contains 65.7 percent barium monoxide (BaO) and 34.3 sulfur trioxide (SO_3) and has a specific gravity of 4.5; witherite contains 77 percent BaO and 22.3 percent carbon dioxide (CO_2). Its specific gravity is 4.3. A high specific gravity gives barite its major use as a weighting agent in drilling muds.

The term "barite," the correct mineralogic name, is derived from the Greek word "barys," meaning heavy. The mineral of commerce is commonly referre dto as "barytes," locally in Missouri as "tiff," and in various other localities as "heavy spar."

Specifications for barite vary with its different uses.

Drillers require the material for oil well-drilling muds to be fine-ground, heavy, and chemically inert; consequently, barite for this purpose must contain a minimum of 92 percent $BaSO_4$, be free of soluble salts, and have a minimum specific gravity of 4.2; 90 to 95 percent of the material must pass a 325-mesh screen. Several percent iron oxide is not objectionable.

Barite for chemical manufacturing must meet more stringent specifications. A minimum of 94 percent $BaSO_4$ and a maximum of 1 percent each for ferrous oxide (Fe_2O_3) and strontium sulfate ($SrSO_4$) and only a trace of fluorine are usually specified. If the material is to be used for lithopone, the $SrSO_4$ content may be somewhat higher. Mesh size is important to chemical producers; if material is too fine dust is lost, and if it is too coarse mixing with carbonaceous material is poor. A size specification range of 4- to 20-mesh is requested by most consumers; however, some purchase lump barite and grind it to this specification.

Glass manufacturers usually require a minimum of 98 percent $BaSO_4$ and a maximum of 1.5 silicon dioxide (SiO_2), 0.15 aluminum oxide (Al_2O_3), and 0.15 Fe_2O_3. In mesh size a mixture ranging from 30-mesh down through 140-mesh is preferred. Material ground to 325-mesh is not desired because it tends to ball up in the batch, but it has been used in times of short supply. Iron is the most objectionable impurity.

Specifications for barite used as a filler or in aggregates are less strict; in most instances mesh size is most important.

TECHNOLOGY

Geology

Most commercial barite deposits are of two types: Replacement deposits, either total or partial, of limestones, dolomites, sandstones, and shales; and residual deposits in which lumps of barite, weathered from deposits of type 1, are enclosed in clays. Barite also occurs as a gangue mineral or associated mineral in metalliferous ores such as lead, zinc, and silver and in mixtures of fluorspar and barite in Kentucky, New Mexico, and elsewhere.

The Arkansas, Nevada, and California deposits are examples of the replacement type.

At Magnet Cove, Ark., barite occurs in a shale. Chert, flint, pyrite, various carbonate minerals, and iron oxides occur dispersed throughout the barite horizon.

Residual deposits include those occurring in Missouri, Tennessee, Georgia, and other Eastern States.

In South Carolina, barite occurs as fissure veins and lenses in a quartz sericite schist and has also been reported occurring disseminated throughout the schist.

Detailed descriptions of various barite deposits are given in the publications listed in the bibliography.

Mining and Milling

The methods of mining and preparing barite depend on the type of deposit and the ultimate use. Residual barite deposits are mined by open pit methods. The clay is removed in log washers, and fine barite contained in the overflow may be recovered by tabling and froth flotation. Barite mined in Arkansas is recovered by both open pit and underground methods. The material is ground and beneficiated by froth flotation. In some locations, barite occurring in veins is mined by shrinkage stoping methods and recovered by jigging.

Barite is ground either wet or dry depending on whether it is to be bleached. For use in well drilling or filler, it is ground dry in ball or Raymond mills. Arkansas material, since it must be floated, is wet-ground. In Georgia, barite is dry-ground in a roll mill. In Missouri, unbleached barite is dry-ground and material to be bleached is wet-ground. Details of the bleaching operations are considered trade secrets, but the general principles are well known. The impurities are brought into solution by treating the ground barite with sulfuric acid; the pulp is then settled and separated and the impurities are washed out. This is followed by drying and packing.

Before being converted to lithopone or barium chemicals, barite is converted into an intermediate soluble form. This is accomplished by roasting crushed barite in a kiln with carbon to reduce barium sulfate to the more soluble barium sulfide, commonly called black ash. The black ash is leached with hot water. To make lithopone, a solution of zinc sulfate is added to the leach liquor and an intimate mixture of barium sulfate and zinc sulfide is produced. This mixture is then filtered, washed, and dried. Blanc fixe is made by adding sodium sulfate to the black ash solution and precipitating barium sulfate. Barium carbonate is manufactured by adding sodium carbonate to the black ash solution and precipitating barium carbonate. Barium carbonate is the starting point for manufacturing various other barium chemicals.

USES

The most important use of barite is as a weighting agent in well-drilling muds. Drilling muds serve several purposes; they lubricate and cool the bit, plaster the walls of the drill hole to prevent caving, carry the cuttings up the well to the surface, and (the purpose for which the barite is used) restrain high gas and oil pressures to their formation levels to prevent blowouts. This type of drilling mud was patented in 1926 and placed on the market under the trade name "Baroid" by National Pigments and Chemical Co. (now National Lead Co.). A royalty of $13 per ton was charged until the patent expired in 1943.

Crushed barite (16- to 20-mesh) is used by the glass industry. This material when added to the glass melt fluxes the heat-insulating froth that forms on the surface of the melt, thus saving fuel, and also acts as an oxidizer and decolorizer, making the glass more workable and increasing brilliance. Fine-ground barite can be used for this purpose when crushed material is not available.

Barite is also used as a filler or extender in paint, inks, oilcloth, linoleum, rubber, and other materials.

Barite is the raw material used in manufacturing lithopone which is used as a white pigment in paints, and various barium chemicals such as barium carbonate, precipitated barium sulfate, barium chloride, barium oxide, barium peroxide, barium hydroxide, barium nitrate, and others.

Blanc fixe, precipitated barium sulfate, is used as a white filler in paints, rubber, inks, and other material where a higher degree of purity is required than is found in the natural barite.

Barium chloride is used in case hardening, in leather and cloth, in making magnesium metal, in preventing scum on brick, and in water treatment. Fused barium chloride may be electrolyzed to produce barium metal.

Barium carbonate is used as a component in ceramic glazes and enamels and also to prevent formation of scum on ceramics. It diminishes porosity and prevents discoloration in bricks and is used in making crown and flint glasses.

Barium oxide is used in glass and in manufacturing barium peroxide. In electric ferrous metallurgy it is used to increase the life of acid furnace linings, give a quieter and steadier arc, and reduce sulfur and slag viscosity.

Barium hydroxide prevents scumming in ceramics and is used in lubricating oils and to

recover sugar from molasses by the barium saccharate process.

Barium nitrate is used in green signal flares, in primers or detonators, and in enamel.

Barium metal is a deoxidizer of copper. It is used as a getter to remove last traces of gas from vacuum tubes, and because of its high electron emission rate when subjected to an electrical potential, it is used in alloys for spark plugs and electron emission elements in electronic tubes.

Barium titanate has become extremely important to the electronic industry because of its high dielectric constant and its piezoelectric and ferroelectric properties. The compound is exceptionally suitable for use in miniature electronic and communication equipment.

Finely-ground barite is mixed with synthetic rubber powder and added to asphalt for road, airstrip and parking lot construction. Advantages claimed by this surfacing material are a more flexible seal coat and less cracking of the surface, thereby giving longer life to the road surface.

Witherite, the natural barium carbonate, is used in refining sugar, manufacturing of barium chemicals, case hardening, and pigments.

BYPRODUCTS AND COPRODUCT RELATIONSHIPS

Some barite has been produced as a byproduct from a lead operation in New Mexico. Barite is frequently associated with fluorspar, but no commercial separation plants are in operation in the United States. However, some barite-fluorite mixtures are used in the glass industry.

Barite, satisfactory for use as a filler in paint manufacture, is separated as a byproduct from the production of acid-grade fluorspar in England.

ALTERNATE MATERIALS

In its largest use, as a weighting agent in drilling muds, barite is preferred to other materials because it is clean to handle, relatively inexpensive, nonabrasive, inert, and has a relatively high specific gravity. During 1926–43, when a royalty was charged on the use of barite in drilling muds, celestite, although having a lower specific gravity (3.95–3.97), was used. It does not now compete in this field. Some iron ores are heavier and in about the same price range as barite; there seem to be no technical reasons why they cannot be substituted, except that they are slightly more abrasive and soil personnel and equipment. Galena, with a specific gravity of 7.4 to 7.6, is much more expensive and has some technical disadvantages. Although substitution appears possible, the use of ground barite in this application is expected to maintain its position.

Lithopone has competition in the pigment field from titanium dioxide. The latter, although about 1 cent per pound higher in price, has largely replaced lithopone.

RESERVES

The domestic commercial reserve of barite ore was estimated by the Geological Survey in 1958 to be about 285 million tons of measured and indicated ore, containing about 46 million tons of barite. The inferred reserve totals more than 365 million tons of ore, containing about 67 million tons of barite. The reserves are principally in Missouri and the southern Appalachian States; the remainder is in Arkansas, Nevada, and California (*2*).[2]

The reserve of chemical-grade barite, because of the strict chemical and physical specifications, is more limited than that of other grades, but requirements can be satisfied with beneficiated ore.

Complete information on foreign reserves is lacking. The Nova Scotian reserve has been estimated in excess of 3 million tons, and that in the region of Camamu Bay, Brazil, in excess of 800,000 tons.

CONSERVATION PRACTICES

Many firms have improved mining methods and initiated flotation processes for the recovery of barite fines previously lost in washer operations. Barite is seldom if ever recovered as a byproduct of metal-mining operations when it occurs as gangue or an associated mineral. There are no estimates of the quantity that has been discarded to dumps or of the present rate at which it is being discarded. A substantial portion of this barite could be recovered if an economical process was available.

In most uses, barite is consumed or incorporated into the product and is not recoverable, the one exception being the material used in drilling muds. In this use some of the barite is lost, but most of it is returned to mud ponds on the surface. Recovery of barite from the mud pond for reuse on deep wells is fairly common practice. However, upon completion of the well, usually the barite in the pond is abandoned.

[2] Italicized numbers in parentheses refer to items in the list of references at the end of this chapter.

SOURCES OF STATISTICAL INFORMATION

The Bureau of Mines annually canvasses the producers of crude barite, ground barite, barium chemicals, and lithopone. Data collected on the crude barite use pattern include quantities used in making crushed and ground barite and in the chemical industry. The Bureau also publishes data on world production. Imports for consumption and exports are compiled from official statistics of the U.S. Department of Commerce.

PRODUCTION, CONSUMPTION, AND TRADE

Domestic production of barite was a record 1,352,000 short tons in 1956 but dropped to a very low 486,000 tons in 1958. Many mines that were inactive in 1958 resumed operations in 1959, increasing production of primary barite to 867,000 tons. During the past 3 years (1961–63), domestic output has remained rather stable with a variation from the mean of less than 10 percent (table 1). Table 2 shows the amount of domestic barite sold or used by producers.

Production of lithopone in the United States has declined. In 1947 there were eight operating plants with sales totaling 165,024 tons valued at more than $17.3 million. Sales dropped to 38,000 tons in 1956 from four operating plants, and by 1958 two more plants were phased out. In 1963 only one firm produced lithopone.

Consumption of ground barite in its major use, drilling mud, increased to a high of 1,421,033 tons in 1956 and then declined slowly to 907,134 tons in 1963. However, there has been some increased use in other industries for ground barite (table 3). Table 4 shows the amount of crude barite used in the manufacture of ground barite and barium chemicals.

Imports have averaged about 640,000 tons for the past 3-year period (1961–63) (table 5). Most of the imported barite is brought into Texas and Louisiana where it is processed in grinding plants for use in well drilling while smaller quantities are delivered to east coast ports for use in the chemical and glass industries.

Crude or otherwise unmanufactured barite is dutiable at $2.55 per long ton. Ground or otherwise manufactured barite has a tariff of $6.50 per long ton levied upon it. Crude witherite is imported duty free, whereas ground witherite has a duty of 12.5 percent ad valorem.

The tariff on barium chemicals varies with each compound. The duties on selected barium chemicals follow:

	Cents per pound
Barium carbonate, precipitated	1.2
Barium chloride	1.6
Barium dioxide	4.8
Barium hydroxide	1.25
Barium nitrate	1.0
Barium oxide	2.0
Barium sulfate, precipitated (blanc fixe)	.625

Other barium compounds are dutiable at 10 percent ad valorem.

[1] Includes barite imported from the United Kingrom valued at $400.

STRATEGIC CONSIDERATION AND GOVERNMENT PROGRAMS

Barite and barium compounds are not on the list of strategic and critical materials to be acquired for the national stockpile. The industry is widely dispersed throughout the Nation; the major concentration is in the center of the country. The United States is potentially self-sufficient; the major problem is mine and plant capacities.

Transportation of imported material during wartime would present a problem; however, since the two major sources of imports are Nova Scotia and Mexico, this problem would be minimized.

On August 1, 1952, the Defense Production Administration set an expansion goal for barite of an annual capacity of 1,360,000 tons by 1955 to meet the needs of the defense program. This program was closed August 11, 1955. No new programs have been initiated since.

PRICES

Barite prices increased steadily from about 1948 to 1958 but have changed little during the last 5 years (1959–63). In 1948 crude barite was priced at about $9 to $10 per short ton; ground well-drilling grade averaged about $17 per ton; and water-ground, bleached barite, in bags, about $35 per ton. In 1958 corresponding prices were $16 to $18 per ton for crude, $26.75 per ton for the ground well-drilling grade, and $45 to $49 for the water-ground bleached material.

The current market prices on barite as quoted in E&MJ Metal and Mineral Markets are as follows (unless otherwise stated, prices are for short tons, f.o.b. shipping point, in carload lots):

Chemical grade:	
Hand picked, 95 percent $BaSO_4$, 1 percent iron	$18.50
Beneficiated, 96 to 97.5 percent $BaSO_4$, 0.3 to 0.7 percent iron	$19.00–23.50
Water ground, 99.5 percent $BaSO_4$, 325-mesh, in 50-pound bags	45.00–49.00
Drilling-mud grade, 83 to 93 percent $BaSO_4$, 3 to 12 percent iron, 4.20 to 4.30 specific gravity:	
Crude	12.00–16.00
Some restricted sales	11.50
Ground	26.75
Imported, bulk, c.i.f. gulf ports	11.00–14.00
Canada:	
Crude, bulk, long tons, f.o.b. shipping point	11.00
Ground, 100-pound bags, short tons, f.o.b. shipping point	16.50

Prices of barium chemicals and lithopone are quoted in the weekly editions of Oil, Paint and Drug Reporter. An annual summary of the prices is published in the commodity chapter of the Bureau's Minerals Yearbook.

Prices of some selected barium chemicals in 1963 were as follows: Barium carbonate, precipitated, bags, carlots, works, short ton $111.50; barium chloride, anhydrous, bags, carlots, works, short ton $176; barium hydrate, crystalline, bags, carlots, truckloads, delivered, short ton $208 to $224; barium nitrate, barrels, carlots, truckloads, delivered, pound $0.16; barium oxide, ground, drums, carlots, truckloads, delivered, short ton $275 to $288; blanc fixe, direct process, bags, carlots, works, short ton $160.

TAXES

Federal tax laws allow barite producers a percentage depletion allowance both domestic and foreign of 15 percent of gross income, not to exceed 50 percent of net income without the depletion deduction. Some producing States levy severance taxes.

TRANSPORTATION

Transportation is an important factor for a relatively low-priced commodity such as barite. It is the low cost of water transportation that permits Nova Scotia barite and other foreign deposits close to water transportation to compete successfully with domestic material on the Atlantic and gulf coasts.

Barite is shipped in bulk and in bags by water, truck, and rail. Some ground material is packed in 100-pound bags and shipped in boxcars to distributors, and some is shipped in bulk in covered hopper cars to oilfield destinations from which it is transported to the wells in specially built trucks.

Crude barite is shipped in bulk, usually in open gondola cars.

Self-maneuvering barges are used for delivering barite and other drilling-mud components to offshore drilling rigs. Material can be transported either in bulk or in bag form; if in bulk it is transferred to the rig pneumatically by hoses, and if in bags by hoists.

RESEARCH

Barite deposits in Arizona, Arkansas, Kentucky, New Mexico, North Carolina, and Tennessee have been investigated and described by the Bureau of Mines (*4*, *7*, *13*, *17*, *18*, *23*, *27*).

Active exploration for new deposits near major consuming centers is underway both here and abroad by industry.

The Bureau has conducted research on processes for separating barite from fluorite and other constituents of complex ores. Continuous flotation tests yielded a barite concentrate containing 91.2 percent $BaSO_4$ with an 85.2 percent recovery. A good grade of fluorspar also was recovered (*8*). Other research by the Bureau included investigation of barite ore treatment methods and processes for making barium and its alloys (*9, 10, 15, 21*). Industry also has been active in barite recovery processes.

Other flotation processes have been reported for the recovery of the barite from ores and drilling fluids (*1, 12, 16, 25*).

Research continues on production, properties, and applications of barium titanate ceramics. The interest in this compound has been created by its dielectric and piezoelectric properties. Barium ferrite ceramics also are being carefully studied. Useful single crystals were grown and their microwave properties were determined.

Research on many other compounds containing barium should ultimately lead to new uses.

OUTLOOK

The barite industry will continue to depend on oil and gas well drilling as the major consuming industry. A current surplus of domestic and foreign petroleum production capacity coupled with rising exploration costs is acting as a brake on new oil exploration activity, which in turn has caused barite consumption to decline. Annual consumption by this industry has fallen from a peak of nearly 1.5 million tons in 1957 to an average of about 0.9 million tons in 1960–63. This production level will probably be held until there is an increase in exploration activity by the petroleum industry.

The decline in barite consumption by its major consumer has been masked by sharp rises in consumption by the paint, glass, and rubber industries. The rise in use by paint and glass manufacturers has been exceptionally sharp, reversing a long-term decline, while use by the rubber industry has risen sharply and continues a long-term upward trend. It is doubtful that the steep rises will be sustained over a long period; the overall outlook is for stabilized or declining consumption.

Imports should capture more and more of the domestic market, especially if tariffs are reduced.

The replacement of lithopone by titanium dioxide as a white pigment should continue, and requirements for barite in this field have been reduced considerably.

If construction of nuclear reactors increased, barite might find greater use as an aggregate in the production of high-density concrete. Barite may also find use as an aggregate material in concrete and in other applications as more knowledge of its characteristics is determined by research efforts.

Increased interest in barite and barium compounds in special applications, such as barium titanate in electrical systems, and barium silicide in gray iron production, may lead to larger markets.

Continued improvement in technical processes is anticipated. A commercial process has been developed for the successful separation of a barite-fluospar ore, providing a marketable grade of both mineral commodities. Such advances lead to increased reserves and utilization of previously undeveloped deposits.

Exploration for new deposits, development of new uses, and research directed toward increasing efficiencies in all steps of barite operations will continue.

PROBLEMS

The outstanding problem of the barite industry is its overwhelming dependence on a single market, the long-term stability of that market being somewhat speculative. Lack of comprehensive research on properties and prospective uses of barite and its derivatives is a retarding factor in developing new markets.

A major long-range problem of the domestic barite industry is that of maintaining a satisfactory reserve position, partly because reserves in residual deposits are difficult to measure. The need for additional barite deposits near major consuming areas is of particular concern, as is the reserve situation of barite suitable for use in chemical applications.

A continuing problem of domestic producers of both barite and barium chemicals is the need for increasing process efficiency to maintain their positions in the market. In some instances better beneficiation methods are needed to meet quality requirements.

To guide both industry and Government agencies in their activities concerning barite, more definitive commodity statistics are needed. The most serious deficiency is lack of statistical detail on end uses.

BERYLLIUM

By Donald E. Eilertsen [1]

BERYLLIUM became commercially important in the United States in the late 1920's. Two U.S. companies are the world's largest consumers of beryl and producers of beryllium metal, alloys, and compounds; their combined sales in 1963 were almost $53 million. Three other companies have small beryllium operations. One of these firms produces small quantities of beryllium mineral flotation concentrate and beryllium compounds, another firm produces electrorefined beryllium from scrap, and the third firm imports and fabricates beryllium from France.

Beryllium has long been famous for its ability to harden copper with steellike strength; beryllium-copper alloys have many industrial applications.

In recent years the Government has become interested in the outstanding nuclear and physical properties of beryllium metal, and it has been subjected to comprehensive research and development. Many new uses for beryllium metal in nuclear energy, high-speed flight, missiles, and space exploration are developing from this research.

Hand-sorted imported beryl from pegmatites is practically the exclusive commercial source of beryllium; the resource of cobbable beryl in the United States is small and not much is known about the foreign resources. One of the pressing problems of the beryllium industry is uncertain resources for the increasing demands.

BACKGROUND

Beryllium, discovered in 1797, was first produced in 1828, simultaneously in France and Germany. The element was first called earth-of-beryl; later, it was called glucinium because of the sweet taste of some of its compounds, and finally the name beryllium was adopted.

The hardening effect of beryllium on copper was discovered in 1926, and its industrial use for this purpose began soon after. Beryllium also was found to have a high melting point and to be exceptionally strong and stiff, despite being nearly as light as magnesium. Another exceptional property, high penetrability by thermal neutrons, led to use in X-ray tube windows.

After World War II the unusual properties of beryllium led to intensive efforts to expand the supply of beryllium minerals and to develop processes to extract, refine, and utilize beryllium for highly specialized structural applications and other purposes. Partly successful, these research efforts are continuing, and seem likely to create a growing use for the metal and its compounds.

[1] Commodity specialist.

SIZE, ORGANIZATION, AND GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

Practically no hand-sorted beryl is produced in the United States at present; all beryl for consumption is imported.

Only two companies in the United States process beryl into beryllium metal prdoucts: The Beryllium Corp., Reading and Hazleton, Pa., and the Brush Beryllium Co., Elmore, Ohio.

The Beryllium Corp.'s net sales in 1963 totaled $28.2 million. The firm produces beryllium metal, beryllium-copper, beryllium-nickel, beryllium-aluminum, beryllium-iron, and various beryllium compounds at Reading, Pa., and Beryllium metal at Hazleton, Pa. This company also has rolling, foundry, and fabricating facilities.

The Brush Beryllium Co.'s sales and service in 1963 totaled $24.3 million. This firm produces beryllium metal, beryllium-copper, beryl-

lium-nickel, beryllium-aluminum, and various beryllium compounds; it also has rolling, foundry, and fabricating facilities.

Three other consumers of beryl are Beryl Ores Co., Arvada, Colo., which produces specialized materials for the ceramic industry; Lapp Insulator Co., LeRoy, N.Y., which uses ground beryl in making high-voltage electrical porcelain; and Champion Spark Plug Co., Ceramic Div., Detroit, Mich., which uses beryl as a minor constituent in special ceramic compositions for spark plugs.

In recent years, Mineral Concentrates and Chemical Co., Inc., has produced small quantities of beryl-bertrandite-euclase flotation concentrate at its Tarryall flotation plant near Lake George, Colo.; the company has utilized some of this material to produce small quantities of various beryllium compounds at Loveland, Colo.

Beryllium Metals & Chemicals Corp. (a subsidiary of Lithium Corporation of America), Bessemer City, N.C., produces electrorefined beryllium from scrap beryllium.

Geneal Astrometals Corp. (mostly owned by The Anaconda Company), Yonkers, N.Y., fabricates beryllium imported from France.

Companies in the United Kingdom, Japan, and France process beryl to beryllium metal, alloys, and compounds.

DEFINITION OF TERMS, GRADES, AND SPECIFICATIONS

Beryllium, the seventh lightest metal, has great stiffness, exceeding other metals including steels; desirable thermal properties, especially for heat-sink applications; a very high strength-weight ratio; and attractive nuclear properties. Some of its properties are atomic number, 4; atomic weight, 9.01; density, 1.84 grams per cubic centimeter; modulus of elasticity, 44 x 10^6 pounds per square inch; melting point, 1,285° C; specific heat, 0.4 calorie per gram per ° C; coefficient of thermal expansion, 11.54 x 10^{-6} centimeter per centimeter per ° C; thermal conductivity, 0.38 calorie per square centimeter per second; electrical conductivity, 40–45 percent of International Annealed Copper Standard; and reflectivity, 55 percent of white light. Beryllium is brittle. Some nuclear properties of beryllium are atoms per cubic centimeter, 1.24 x 10^{23}; neutron scattering cross section, 6.9 barns per atom; and neutron absorption cross section, 0.009 barn per atom.

Beryl ($3BeO \cdot Al_2O_3 \cdot 6SiO_2$) when pure contains about 14 percent beyllium oxide (beryllia or BeO) or about 5 percent beryllium metal (Be). Commercial beryl is hand-sorted or cobbed crystals and lumps of beryl usually containing about 11 percent BeO, or 4 percent Be.

Beryl is bought on a basis of short ton units of contained BeO, a unit being 1 percent of a short ton, or 20 pounds. The price per ton of beryl is determined by the number of short ton units of contained BeO in a ton of beryl, multiplied by the corresponding unit value for concentrate of that particular BeO content. The price may be computed quickly by multiplying the percentage of BeO by its corresponding unit value; for example, the price per ton of beryl having 11 percent BeO and a value of $25 per short ton unit of BeO would be $275.

Beryllium-copper master alloy contains 4 percent beryllium, the remainder being copper. This alloy is remelted with additional copper to obtain beryllium-copper alloys of lower beryllium content.

Toxicity (*2, 4*)[2]

Some forms of beryllium are known to be toxic, but many years of research are needed to learn about beryllium-associated diseases. No ill effects have developed in mining, storing, and transporting beryl, but precautions should be taken in handling some beryllium minerals, especially certain forms of bertrandite which are soluble in dilute acid and possibly sufficiently soluble in body fluids to cause dermatitis.

No one is known to have been poisoned from ingestion of beryllium compounds, or to have contracted dermatitis or pneumonitis from handling or mechanically working low-beryllium alloys such as beryllium-copper alloys. Dermatitis may occur from coming in contact with soluble beryllium compounds, and acute pneumonitis may develop from inhaling mists, dusts, or fumes from these compounds and from melting the metal and its alloys; the ill effects sometimes develop slowly over many years.

Modern control practices have practically eliminated new cases of beryllium disease. Much has been done by the beryllium industry to prevent the disease. Working places are kept clean, workers are required to wash their hands frequently, clothing is laundered regularly, dusts, fumes, and mists are caught at the source and deposited in dust collectors, and numerous other precautions including medical programs have been adopted to make working conditions safe.

[2] Italicized numbers in parentheses refer to items in the list of references at the end of this chapter.

TECHNOLOGY

Mineralogy and Geology

The earth's crust is estimated to contain 6 parts per million (ppm) of beryllium, compared with 0.1 ppm of silver and 16 ppm of lead. Beryllium occurs as an essential constituent in approximately 40 minerals, and as an occasional constitutent in 50 other minerals (*6, 8*). Beryl, bertrandite, phenacite, barylite, and chrysoberyl are some of the most commonly known beryllium minerals, but beryl is practically the sole commercial source of beryllium.

The world's principal commercial sources of beryl are heterogeneous granite pegmatites, where the mineral occurs in enriched zones, filled fractures, and replacement bodies. Homogeneous pegmatites have yielded little beryl. The principal beryl deposits are found in zones that usually contain only a few thousand tons of pegmatite rock; however, some deposits contain a million tons or more of rock. Certain zones in some pegmatites contain more beryl than others. Sometimes beryl is found in shoots that are parts of zones. When beryl occurs in zoned pegmatites the largest crystals usually are near the core and the fine grained crystals near the outer zone.

Promising quantities of beryllium have also been found in various nonpegmatite deposits. At Spor Mountain, Utah, bertrandite occurs erratically in altered tuff associated with fluorite, montmorillonite, opal, and chalcedony. Similar deposits have been found in the Honeycomb Hills, Utah. In White Pine County, Nev., phenacite and bertrandite occur with scheelite, fluorite, pyrite, and other minerals in limestone. In Park County, Colo., beryl and bertrandite occur with fluorite in mica-quartz greisen along the contact with granite. At Seal Lake, Labrador, Canada, barylite occurs in veinlets with quartz and albite. In northern Coahuila, Mexico, bertrandite was found in fluorite which contained other minerals such as quartz, kaolinite, and hematite.

Mining

Occasionally pegmatites are mined for beryl alone, but more often beryl is recovered as a coproduct or byproduct while recovering other minerals such as feldspare, mica, lithum minerals, columbite, tantalite, and cassiterite. Deposits often contain less than 100 tons of cobbed beryl; however, some deposits yield several thousand tons of beryl.

Some pegmatite deposits are mined on a small scale, usually by crude opencut methods. Mining is begun on an outcrop where the minerals of value can readily be seen, and cuts are made or pits are sunk by drilling and blasting the rock. Hand-drilling methods are sometimes used in out-of-way places, but usually air-driven drills are used. The blasted rock is hand-cobbed to recover valuable minerals including beryl, and the waste rock is discarded.

The cycle of drilling, blasting, cobbing for valuable minerals, and hauling waste to dumps is repeated until the operation cannot be worked economically. Sometimes the blasted rock is coarsely crushed and passed over belts so that valuable minerals can be sorted from it. The balance of the rock may be reduced further in size for concentrating the associated valuable minerals. Where conditions warrant, mechanized mining methods are used.

Milling

Beryl, feldspar, and some other pegmatite minerals have densities so nearly the same that it is difficult to separate beryl by mechanical methods. Flotation methods have produced beryl concentrates on a laboratory scale, but it has been difficult to produce material on a commercial scale to equal the quality, price, and ease of obtaining hand-sorted beryl. Consequently, all commercial beryl is hand-cobbed, and seldom are crystals and fragments recovered less than 1 inch in size. Probably not more than one-third of the beryl in the average commercial deposit is recovered by the crude hand methods now employed.

Recent discovery of important resources of bertrandite in clay formations in Utah aroused great interest, and studies on this material indicate that hydrometallurgical procedures may have to be employed to extract beryllium compounds directly from the ore, because beneficiation methods do not appear to work satisfactorily.

Preparation of Beryllium Oxide and Beryllium

Several methods for converting beryl to beryllium oxide have been developed. The Copaux-Kawecki fluoride process is used by The Beryllium Corp., and the Sawyer-Kjellgren sulfate process is used by The Brush Beryllium Co.

In the Copaux-Kawecki fluoride process beryl containing 10 to 12 percent BeO is crushed, ground in a wet ball mill to minus 200-mesh, and filtered. It is then mixed in batches with soda ash, sodium silicofluoride, and sodium ferric fluoride and made into briquets. The briquets are dried, sintered, cooled, crushed, and ground in a wet pebble mill to which hot water is added,

and the slurry is pumped to a tank for leaching. More water is added and the mixture is agitated, leached, and allowed to settle. The liquid, containing soluble sodium beryllium fluoride, is decanted to separate it from the solids, which contain aluminum and iron oxides and silica. Caustic soda is added to the heated solution to precipitate beryllium hydroxide, which is filtered and calcined to convert it into beryllia (*1*).

The Sawyer-Kjellgren process is based on the discovery that if melted beryl is quenched in cold water the resultant frit reacts with sulfuric acid. The beryl, containing 10 to 12 percent beryllia, is crushed, dried, and melted in an electric arc furnace. The melted beryl is poured into water to obtain frit, which is dry-ground in a ball mill to a fine powder. Batches of the powder are mixed with concentrated sulfuric acid, steamed, and agitated. Water and more steam are then added to the slurry. The liquid, containing soluble beryllium and aluminum sulfates, is filtered from the sediment and pumped to a tank where ammonium hydroxide is added. The filtrate from this operation is further treated with a chelating agent to prevent impurities from precipitating upon subsequent addition of caustic soda. Hydrolysis follows, and the precipitate, beryllium hydroxide, is filtered off. This precipitate is ignited in an electric furnace to form beryllium oxide (*4, 9*).

The beryllium products of either the Copaux-Kawecki or the Sawyer-Kjellgren process generally have to be purified to produce beryllium metal.

The oxide or hydroxide can be dissolved in ammonium bifluoride solution and heated to boiling, and calcium carbonate flour is added to precipitate aluminum (*9*). Lead dioxide is added to remove manganese and chromium, and the resultant slurry is filtered through pressure filters using stainless steel screens precoated with rayon fiber. Lead, nickel, and copper are next removed from the filtrate with ammonium polysulfide. After being filtered again, the solution is evaporated, and pure ammonium beryllium fluoride is recovered by crystallization. This fluoride is then thermally decomposed to beryllium fluoride, while the ammonium fluoride is volatilized.

Beryllium metal is produced by the reduction of beryllium fluoride with magnesium metal. This is usually done in batches in a high-frequency induction electric furnace provided with a graphite crucible (*3–4, 9*). An excess of beryllium fluoride must be used to keep the highly exothermic reaction under close control. When reduction of the batch has been completed, the temperature is raised to about 1,300° C to melt the beryllium and allow it to coagulate into a pool at the surface of the slag. After cooling, the solid beryllium is separated from the slag, and the slag is leached to recover its beryllium content. The metal is remelted in a vacuum, which volatilizes slag occlusions and small amounts of impurities such as magnesium.

Preparation of Beryllium-Copper Master Alloy

To prepare beryllium-copper master alloy, weighed quantities of beryllium oxide, carbon powder, and copper are mixed in batches and melted in an electric arc furnace (*1*). The product is impure beryllium copper. Additional refining or other treatment removes the carbon and gases absorbed during reduction. The final product contains about 4 percent beryllium and is called beryllium-copper master alloy.

USES

One of the earliest uses for beryllium was as windows in X-ray tubes. Interest for beryllium grew rapidly with the coming of nuclear energy and the advent of high-speed aircraft, missiles, and space exploration. Beryllium's unique nuclear properties quickly attracted interest for testing and using the metal in nuclear reactors as moderator and reflector material, as neutron source material, and possibly as a canning material for fuel elements. Quantities of beryllium used in individual reactors range from a few pounds in Systems for Nuclear Auxiliary Power devices to 3,500 pounds in the Advanced Test Reactor; some reactors do not contain beryllium. Beryllium's unusual physical properties, especially high stiffness, high heat capacity, and low density, aroused substantial interest among scientists in 1957, and shortly thereafter extensive research and development began. Much of this work is still in progress.

Numerous uses for beryllium are gradually emerging from these intense studies. The metal is used in gyroscopes, accelerometers, parts of inertial guidance systems for high-speed flight and marine navigation, airplane brakes, heat shields such as those used in the *Freedom 7* and *Friendship 7* space capsules which orbited the earth, and shingles such as those used on the outside of the *Aurora 7* space capsule. Other applications for beryllium include a gold-plated beryllium antenna on *Telstar I*, intricate plates for Gemini (two-man) space capsules, large extruded tubing for the Project Saturn rocket program, and spacers, penetration aids, and various other sections in missiles. Recently reported uses include rotor blades and various other parts for gas turbine engines, solar cell mounting boards for satellites, and mirrors and

other optical parts. The winning car in the Indianapolis 500-mile race on Memorial Day 1964 had beryllium brakes. The list of uses for beryllium metal is growing; many important uses for beryllium are still on drawing boards or in the development stage. Among these is the use of beryllium for propulsion.

The industry was founded on the ability of beryllium to harden and strengthen some soft and ductile metals and alloys, and a major use for beryllium has been in this field. Most notable are the beryllium-copper alloys. These have many special qualities including high strength; excellent castability, formability, and machinability; high electrical and thermal conductivity; high resistance to corrosion and fatigue; stability under load; low creep-tendency; and antisparking and nonmagnetic qualities. Copper containing approximately 1.9 percent beryllium offers maximum strength and hardness; 0.4 percent beryllium, high conductivity; and 1.2 percent beryllium, midway properties. Some of these alloys contain small amounts of a third element such as nickel or cobalt. Beryllium-copper is available in wrought, cast, or forged form.

Beryllium-copper has a long list of uses; they include springs, bellows, diaphragms, electrical contacts, aircraft engine parts, plastic molds, marine propellers, gears, bearings and bearing retainer rings, shims, precision castings, and rollers. Beryllium-copper is also finding numerous applications in miniature electrical and electronic components.

Some new uses for the alloy include housings to protect undersea telephone systems, automobile starter springs, bucket wheels used in instruments to measure the velocity of water, and antennas for space vehicles and satellites. Space capsule *Sigma 7* contained an antenna consisting of tightly wound beryllium-copper ribbon that ejected to form a tubing 16 feet long. The *Lofti* and *Traac* satellites have this type of antenna. Other antennas were designed to eject as much as 1,000 feet of 0.5-inch-diameter tube from the ribbon.

Beryllium-nickel alloys are heat treatable and resemble stainless steels in many respects. Uses for beryllium-nickel alloys include surgical instruments, matrix for diamond drill bits, parts for fuel pumps and business machines, and dies for shaping aluminum channels, necks of bottles, stainless steel dinnerware, and plastics.

Beryllium also is used as an alloying constituent to improve the processing and properties of light metals. New beryllium-aluminum alloys containing mostly beryllium are available and are attracting attention.

Beryllium oxide has applications in nuclear reactors and in a wide variety of commercial applications, particularly ceramic parts for the electronic industry.

Besides being the commercial source of beryllium, beryl has ceramic applications in high-voltage electrical porcelains, suspension insulators, and spark plugs.

ALTERNATE MATERIALS

Uses for beryllium metal are gradually developing and it is quite likely that where beryllium has replaced other metals those metals can to a certain extent again be used in place of beryllium. Although beryllium has the lowest termal-neutron cross section of all the metals, magnesium, zirconium, aluminum, and stainless steel are alternate materials in the nuclear-energy field and each has superior qualities for certain applications.

An alloy containing 20 percent manganese, 20 percent nickel, and 60 percent copper is reportedly a good substitute for beryllium-copper in springs, diaphragms, and spark-resistant and antimagnetic tools, but not in applications where electrical conductivity is important.

Phosphor bronze can be used in place of beryllium-copper, particularly in manufacturing springs and diaphragms, but it is only about half as strong and half as conductive of electricity as 2 percent beryllium-copper. Aluminum bronze was used before the development of beryllium-copper alloys in making nonsparking tools, especially those which did not require cutting edges.

Aluminum bronze containing nickel can be hardened by heat treatment and is a fair substitute for beryllium-copper in cutting tools. Stainless steels and special alloy steels could be used in a few instances as substitutes, but none of these performs in all respects as well as beryllium-copper.

RESERVES

The beryllium reserves in the United States have been studied by the industry and Government for potential beryllium for many years, particularly since 1958. Although beryl reserves in pegmatites in the United States are fairly well known, there are few data on world reserves. The beryllium reserves of nonpegmatites are known for a few deposits; world deposits have received scant attention.

The U.S. reserves of beryl in pegmatites vary greatly with the grade and size of deposits (*5*). For example, one estimate shows a reserve of 8,800 tons of beryl (440 tons of beryllium) in deposits containing at least 1 percent beryl and at least 100 tons of beryl. Approximately 75 percent of this beryl is in New England and

South Dakota. Another estimate shows a reserve of 216,000 tons of beryl (10,800 tons of beryllium) in deposits containing 0.2 to 1 percent beryl and at least 100 tons of beryl. More than 90 percent of this beryl is in the tin-spodumene belt of pegmatites, 25 miles in length and up to 2 miles in width, extending through Kings Mountain, N.C. The pegmatites in this belt were reported to contain 823,000 tons of beryl (41,000 tons of beryllium) to a depth of 300 feet, the pegmatite containing about 8 pounds of disseminated beryl per ton of rock.

The world reserve of beryl in pegmatites is not known. An inquiry made in 1959 by the U.S. Government indicated that most countries that supply the United States with hand-sorted beryl could produce more beryl if needed and substantially more beryl if prices were higher. In many instances the investigation revealed that resources of hand-cobbed beryl were being depleted rapidly. Very few firm data on beryl reserves were obtained because the occurrence of this mineral is unpredictable.

In recent years interest has focused on nonpegmatitic sources of beryllium. Promising deposits of beryllium have been found in several localities, and those in the Spor Mountain area in Utah and the Mount Wheeler area in Nevada have aroused appreciable interest. Various firms are studying the feasibility of recovering commercial beryllium, particularly from the Spor Mountain deposits. Tentative estimates by the Geological Survey, U.S. Department of the Interior, indicate that tuff in the Spor Mountain area and quartz monzonite in the Gold Hill area in Utah exceed 15 million tons of ore containing 0.5 percent BeO (27,000 tons of beryllium). The Mount Wheeler area in Nevada was tentatively reported to contain 500,000 tons of bertrandite and phenacite ore containing 0.5 percent BeO (900 tons of beryllium). (7)

Other beryllium deposits that have attracted widespread attention are those in the Lake George district, at the western edge of the Pikes Peak granite batholith in Park County, Colo.

Elsewhere in the world, new nonpegmatitic beryllium deposits in Labrador and Mexico have attracted unusual attention. Deposits in the Seal Lake area of Labrador (about 100 miles northwest of Goose Bay) were tentatively reported to have 3 million tons of barylite ore containing 0.5 percent BeO (5,400 tons of beryllium). Deposits in the Aquachile area of Mexico (80 miles southwest of Marathon, Tex.) reportedly contain substantial bertrandite ore.

SOURCES OF STATISTICAL INFORMATION

Data on the domestic production and consumption of beryl and the production of beryllium metal alloys and compounds are collected by the Bureau of Mines through industry canvasses. Statistical data on imports and exports of beryl and beryllium products are obtained from the Bureau of the Census, U.S. Department of Commerce. Data on world production of beryl are compiled by the Bureau of Mines from information supplied by Foreign Service dispatches, from official publications of the mining departments of the respective countries, and from other sources. Enough statistical information is available at present on beryl, beryllium metal, alloys, and compounds for the present needs of the Government, industry, and the public.

PRODUCTION, CONSUMPTION, AND TRADE

Domestic production of hand-sorted beryl has always been small in the United States. Prior to 1953 the 15-year annual average was 255 tons, but during the following 10 years (1953–62) the annual average rose to 446 tons, mostly because the Government paid incentive and premium prices for domestic beryl during this period. Approximately 200 operations produced beryl in 1957. In 1963, after the Government stopped paying premium prices, only 1 ton of beryl was produced.

A total of 4,456 tons of domestic beryl was produced during 1953–62, and 3,276 tons of this was sold to the Government for incentive prices. The 14 States producing beryl during this period, in descending magnitude, were South Dakota, Colorado, New Mexico, Maine, New Hampshire, Connecticut, Georgia, Arizona, Wyoming, North Carolina, Maryland, New York, Idaho, and Virginia.

In addition to hand-cobbed beryl some select low-grade ore, mostly beryl-bertrandite-euclase, was produced in Colorado; the outputs were 42 tons in 1958, 97 tons averaging 4.44 percent BeO in 1959, 265 tons averaging 5 percent BeO in 1960, 805 tons averaging 3.37 percent BeO in 1961, 760 tons averaging 3.05 percent BeO in 1962, and 750 tons averaging 3 percent BeO in 1963.

During 1959–63, 22 countries produced beryl; the annual output ranged between 6,650 and 12,000. The eight largest producers were Brazil,

Argentina, Mozambique, the U.S.S.R., Uganda, the Malagasy Republic, Southern Rhodesia, and India.

Production data on outputs of beryllium metal, alloys, and compounds are company confidential.

Beryl consumptions in the United States during 1959–63 were 8,173 tons in 1959, 9,692 tons in 1960, 9,392 tons in 1961, 7,758 tons in 1962, and 7,934 tons in 1963. Almost all of this beryl was utilized to produce beryllium metal, alloys and compounds.

Beryllium ore and concentrate are imported duty free. Unwrought beryllium is dutiable at 17 percent ad valorem; beryllium-copper master alloy, 1.275 cents per pound plus 20 percent ad valorem; and beryllium oxide and carbonate, 10 percent ad valorem.

Import and export data on beryllium for 1959–63 are shown in table 1.

TABLE 1.—*Beryllium imports and exports*

Year	Imports [1]		Exports [2]			
	Beryl (short tons)	BeO or $BeCO_3$ (pounds)	Beryl (short tons)	Beryllium and beryllium alloy (except beryllium-copper) metal powders (pounds)	Beryllium metal and alloys (except beryllium-copper) in crude form and scrap (pounds)	Beryllium and beryllium alloys in semi-fabricated forms, n.e.c. (pounds)
1959	8,038	906	----------	5,519	153,428	5,313
1960	8,943	2,603	7	9,166	102,264	6,062
1961	8,516	3,281	----------	1,815	120,830	692
1962	8,552	19	----------	1,260	60,468	1,217
1963	6,243	200	1	6,015	93,034	774

[1] Data on unwrought and wrought beryllium imports were not available prior to September 1963.
[2] Separate data on beryllium-copper alloy exports were not available.

Starting in September 1963, additional data on beryllium imports became available. These additional imports for September–December 1963 were 2,110 pounds of other beryllium compounds, 31,888 pounds of unwrought, waste, and scrap beryllium, and 13 pounds of wrought beryllium.

STRATEGIC CONSIDERATIONS

The beryllium industry depends wholly on imported beryl for its commercial source of beryllium.

Beryl and beryllium-copper master alloy are stockpiled under the Strategic and Critical Materials Stockpiling Act of 1946 (Public Law 520, 79th Congress). Both the basic and the maximum objectives of this program have been achieved.

Government inventories of beryl, beryllium, and beryllium-copper master alloy on December 31, 1964 are shown as follows:

Material	Strategic stockpile, stocks	Defense Production Act, stocks	Commodity Credit Corporation, stocks	Supplemental stockpile, stocks	Total stocks
Stockpile-grade beryl, tons	23,230	2,086	[1] 6,183	18,212	[1] 49,711
Nonstockpile-grade beryl, tons	----------	456	----------	----------	456
Upgraded materials from some of the above stockpile-grade beryl:					
Beryllium-copper master alloy, tons	1,075	----------	6,312		7,387
Beryllium metal, tons	----------	----------	153		153

[1] Includes 6,000 tons of beryl on order.

GOVERNMENT PROGRAMS

The Office of Minerals Exploration, U.S. Department of the Interior, offers financial assistance up to 50 percent of approved costs to explore for all types of beryllium ore.

Under the Agricultural Trade Development and Assistance Act of 1954 (Public Law 480, 83d Cong.) The Commodity Credit Corporation, U.S. Department of Agriculture, occasionally barters surplus agricultural commodities with certain countries for strategic materials including beryl, beryllium, and beryllium-copper for the supplemental stockpile.

PRICES

Prices for domestic and imported cobbed beryl are on a buyer and seller basis. The average price of imported beryl containing approxi-

mately 11 percent BeO at ports of exportation for 1964 was $253 per short ton, or about $23 per short ton unit of BeO.

In December 1964 American Metal Market quoted the price of beryllium metal, 97 percent pure, beads, f.o.b. Reading, Pa., and Cleveland, Ohio, at $62 per pound in 1,000- to 2,000-pound quantities. A blend of beryllium powder, 200-grade, was quoted at $54 per pound in quantities of 20,000 pounds. Vacuum-cast beryllium ingot was quoted at $67 to $71 per pound. Beryllium-copper master alloy was quoted f.o.b. Reading, Pa., Detroit, Mich., and Elmore, Ohio, at $43 per pound of contained beryllium with copper paid for at the market price on date of shipment. Beryllium-copper strip, rod, bar, and wire were quoted at $2.04 per pound. Beryllium-aluminum was quoted at $65 per pound of contained beryllium with aluminum paid for at the market price. Beryllium-magnesium-aluminum was quoted at $60 per pound of contained beryllium with magnesium and aluminum paid for at the market price.

The Brush Beryllium Co. quoted the prices of UOX and GC–R beryllium oxide powders, minus 20-mesh and dry screened, at $12 to $15 per pound, depending on the quantity.

TAXES

Depletion allowance is 23 percent for domestic producers of beryl and 15 percent for U.S. producers in foreign countries.

RESEARCH

Beryllium metal has been undergoing thorough research in recent years. Industry and the Government, especially the Atomic Energy Commission, Armed Forces, and U.S. Department of the Interior, have kept beryllium high on the list of materials for intensive study, the subjects of which range from resources through extraction, purification, fabrication, properties, and development of uses. Much of the research has been completed, but much remains to be done. Bureau of Mines work on beryllium has included a nationwide study of the beryllium potential in domestic mineral resources and research on the development of mineral beneficiation methods and on methods to extract, purify, and fabricate beryllium, the resource studies being almost completed. Numerous Reports of Investigations have been published.

OUTLOOK

Extensive research and development have been underway on beryllium since 1958 and will strongly influence the use pattern and growth rate of the beryllium industry. Commercial use of beryllium and its alloys will expand moderately, but the major short-term growth of beryllium metal will be in defense, atomic energy, and space exploration applications.

The hand-sorted beryl supply may be inadequate to satisfy long-term and greater demand for beryllium alloys, compounds, and metal. In the near future beryllium will probably be extracted directly from bertrandite ore or from mill concentrate of beryl, phenacite, bertrandite, or other beryllium minerals in sufficient quantity to supplement imported hand-sorted beryl.

Attention will be directed increasingly to the world's potential resources of beryllium in low-grade deposits, and the expectation is that deposits will be found and developed in the United States that will be able to fulfill domestic needs in an emergency. It is not clear whether U.S. deposits now known will be commercially competitive with foreign beryl mines, because there is too little knowledge of the extent and grade of resources in other countries.

International competition for beryllium markets may become more noticeable when demands for beryllium products increase.

PROBLEMS

A main problem of the industry is to determine how best to gain advantage of newly discovered qualities of beryllium in finished products. Much more diversified use of beryllium is needed to fully determine uniformity of mill products and advantages for using the metal. Currently produced beryllium is brittle and reported to be ready for prototype structural elements but not for large-scale use in major aircraft components.

In seeking to develop additional beryllium supplies, it should be recognized that longtime adequacy of supply from hand-cobbed beryl derived from pegmatite deposits has dulled commercial interest in other, less easily recognizable sources. Until recently, knowledge of beryllium occurrences has not been sought intensively. Comprehensive detailed knowledge of the nature of beryllium concentrations in the earth's crust is needed. Vigorous and rapid

pursuit of this problem is warranted, since all discoveries are potential commercial competitors, and new information may profoundly influence decisions based on prior knowledge. As facts are found, intensive exploratory efforts may be assigned to the most promising discoveries.

The attractive combination of properties that beryllium apparently offers as a structural material has tended recently to detract attention from possible uses of the element in compounds and alloys. For example, beryllium oxide is of special interest both as a source of the metal and because of its refractory and nuclear properties. Great demands for beryllium products would intensify the resource and mining problems and would compel turning to poorer deposits for supply, thus increasing the difficulties of the extractive metallurgists.

Dusts and fumes from beryllium and numerous beryllium compounds are toxic to humans, and great caution must be exercised when one is exposed to these substances.

BISMUTH

By Donald E. Moulds[1]

BISMUTH, known initially for its medicinal properties, today is noted chiefly for its metallurgical ability to impart desirable qualities of fusibility, castability, and machinability to a wide variety of industrial alloys.

The metal is obtained as a byproduct in processing ores of other metals containing minor quantities of bismuth. Byproduct sources have provided an increasing supply in recent years to meet the world requirement of over 6 million pounds annually. Peru, Mexico, Bolivia, Canada, and the Republic of Korea are the major suppliers of bismuth in ores, and concentrates. Several other countries, such as Japan and the United States, are large producers of refined metal from imported raw materials.

The United States is the largest consumer of bismuth and is dependent on foreign sources for some 90 percent of its requirements, either in the form of imported base metal ore and bullion or in the form of refined metal and alloys. Peru, Mexico, and Canada are the chief suppliers to the United States. Three lead refineries currently produce all of the domestically refined bismuth.

The degree of dependence on foreign sources of supply and the many essential industrial and medicinal uses classify bismuth as a strategic and critical material. Inadequate data on domestic production and bismuth content of domestic ores hamper determination of domestic bismuth potential.

The outlook for bismuth is one of continued growth in consumption, especially in the field of industrial alloys and chemicals, in step with rising national industrial activity. Development of new applications is expected, but these are not anticipated to require large quantities of bismuth.

BACKGROUND

The association of bismuth with ores of other metals and its affinity for these metals in medieval metallurgical processes caused the white substance found with lead and tin in smelting to be referred to by early writers as imperfect tin, as female antimony, or as an imperfect form of lead.

Undoubtedly bismuth-lead and bismuth-tin alloys formed in conjunction with lead and tin metal were recognized and used prior to the Middle Ages. In the 15th century Basil Valentine referred to the substance as "wismuth," and at the end of the 16th century Georgus Agricola, the early mineralogist, latinized the German name to "bisemutum." About 1597, the efficacy of bismuth nitrate in treatment of intestinal disorders was discovered by Andreas Libavius. It was not, however, until the 18th century that J. H. Pott, C. J. Geoffrey, and T. Bergman produced the pure metal, demonstrating it to be a distinct element similar in many respects to lead (*3*).[2]

Bismuth initially was produced by smelting bismuth-rich ores with suitable fluxes to produce a crude metallic bismuth. The association of bismuth with base metal ores and the fact that it accompanies lead through the smelting and refining operation has permitted extraction to be concentrated at lead refineries. Beginning in 1833 with the Pattison process for debismuthizing lead bullion (*6*), continued development and improvement of metallurgical processes for extraction and purification of bismuth have resulted in a commercially available bismuth metal of 99.995-percent purity.

Bismuth as a compound was noted initially for its soothing effect on human digestive disorders and its healing effect on wounds and sores. This property of bismuth was exploited in many medicinal and cosmetic preparations, which up to 1930 used some 90 percent of the bismuth consumed. The development of low-melting alloys has resulted in a wide variety of industrial applications of bismuth alloys and chemical compounds. While advances in medical technology have made many medical uses of bismuth obsolete, the industrial and chemical developments have resulted in a continuing growth in consumption.

[1] Commodity specialist.

[2] Italicized numbers in parentheses refer to items in the list of references at the end of this chapter.

SIZE, ORGANIZATION, AND GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

World production of bismuth is about 6.5 million pounds annually. As output is derived as a byproduct of processing ores of other metals, the bismuth-producing industry is distributed among all of the countries having metal-refining facilities. The major producing countries are Bolivia, Canada, Japan, Mexico, Peru, the Republic of Korea, and the United States. Approximately three-fourths of the world supply is contributed by these countries; Peru is the largest supplier with some 20 percent of free world output. United States production of refined bismuth is confined to three companies operating bismuth refineries in conjunction with lead refining plants; American Smelting and Refining Company, Omaha, Nebr., United States Smelting Lead Refinery, Inc., East Chicago, Ind., and United Refining & Smelting Co., Chicago, Ill.

Bismuth is consumed in the manufacture of products in all of the industrial nations. While consumption statistics are not available on a comparative basis, the United States is the leading consumer with requirements approximately one-third of world production. Other large consuming countries are those of Western Europe, Japan, and the U.S.S.R. The industry can be roughly divided into companies manufacturing chemical compounds and companies manufacturing alloys. Bismuth is consumed in 23 States with New York by far the largest consuming area. Some 60 companies predominantly in the eastern and Mississippi Valley industrial areas account for over 80 percent of the annual consumption.

DEFINITION OF TERMS, GRADES, AND SPECIFICATIONS

Bismuth is a soft, heavy, coarsely crystalline metal having a tinny or silvery-white color tinged with red. Its atomic number is 83 and its atomic weight is 209. The specific gravity is 9.80 at 20° C. but is 10.067 in the molten state. Pure bismuth boils at 1477° C. but its melting point is low (271° C.), and it forms alloys with lead, tin, antimony, cadmium, and indium which melt at temperatures as low as 47° C. The thermal conductivity of solid bismuth is less than that of any other metal except mercury. Similarly, it is a poor conductor of electricity and is the most diamagnetic metal known. Its absorption cross section for thermal neutrons is the lowest of all metallic elements except beryllium (*3*).

The term "bismuth" commonly refers to refined metal; although there are no standard specifications, cast bismuth often assays 99.999 percent pure. The pharmaceutical trade employing bismuth for medical purposes demands a minimum purity of 99.99 percent and absolute freedom from arsenic. The following is a typical chemical analysis of commercially available bismuth:

	Percent
Bismuth	99.995
Lead	.0001
Copper	.0002
Silver	.0001
Iron	.0001

National Stockpile Specification P–7, which covers metallic bismuth suitable for production of bismuth-bearing alloys and bismuth salts, requires that all material shall have a minimum bismuth content of 99.99 percent.

TECHNOLOGY

Geology

It is estimated that the bismuth content of the earth's crust is 1 part in 10 million. Compared with aluminum, bismuth is indeed a rare metal. The composition ratio is about 2.5 pounds of bismuth to 1 million pounds of aluminum. Despite the quantitative scarcity, the frequency of occurrence of bismuth is remarkably high. The bismuth minerals, bismite (Bi_2O_3) and bismuthinite (Bi_2S_3), are widely distributed in small quantities in ores throughout all the continents. Native bismuth is not an uncommon constituent of hydrothermal veins in some mining localities such as Cordoba Province, Spain.

Because of the uneconomic concentration of bismuth in nature, practically no deposits can be mined for the bismuth content alone. Most is produced as a byproduct from mining and processing ores of lead, copper, tungsten, gold, and other metals containing minor quantities of bismuth.

Metallurgy

Bismuth minerals occasionally occur in sufficient quantity so that upgrading by hand sorting or gravity and flotation methods results in a bismuth-rich concentrate. Bismuth occurring as a sulfide or carbonate can be recovered from these concentrates by direct smelting in a reverberatory furnace with suitable fluxes to produce a crude metallic bismuth, matte, and slag. The crude bismuth requires further refining, while the matte is resmelted. Bismuth occurring as an oxide or carbonate commonly is recovered by leaching the ore with hydrochloric acid in earthenware vats and precipitating bismuth oxychloride by diluting the pregnant solution with water. Repeated cycles of

dissolution, precipitation, and removal of copper with scrap iron yield a purified oxychloride which is melted with charcoal and lime to yield a crude metallic bismuth for further refining. This method is also commonly used for recovery of bismuth from roasted tin concentrate and other bismuth-bearing materials.

Ore-dressing procedures employed for concentration of lead and copper minerals prior to smelting also concentrate the associated bismuth minerals. In many respects, bismuth acts similarly to lead in the usual smelting operations employed in treating copper and lead ores and thus collects with the lead. In the copper smelter, the lead and bismuth are volatilized and accompany the dust and fume produced by the melting furnace and converter. Copper smelters that treat ores containing lead and bismuth are usually equipped with a baghouse or a Cottrell precipitator to collect the dusts and fume. These products are then sent to the lead-smelting plants for treatment. The bismuth in lead ores, concentrates, and flue dust and fume is collected in the lead bullion during lead-smelting operations. Bismuth is considered to be a detrimental impurity in refined lead and if present in excessive amounts must be removed before the lead can be used for many applications (*1*).

The two most important methods used to remove bismuth from lead bullion are the Betts process and the Betterton-Knoll process (*2*). In the Betts process, cast anodes of lead bullion are electrolyzed in a lead fluosilicate to yield a pure lead cathode and an anode residue containing bismuth. The residue is melted to produce a metal alloy and a slag. The alloy containing the various metals is selectively oxidized to remove arsenic, antimony, and lead while the bismuth remains in the slags. The bismuth-rich slag is fluxed and reduced with carbon to a copper matte and crude bismuth metal.

In the Betterton-Knoll process used for recovery of over 90 percent of U.S. production, the lead bullion is first softened and desilverized by the Parkes process (*5*) to remove a silver-zinc insoluble segregate. Magnesium and calcium are added to the melt, the mass is cooled to near the melting point of lead, and a high-melting calcium-magnesium-bismuth dross is removed. The dross is liquated to melt as much entrained lead as possible; the residue is melted in a reverberatory furnace, treated with chloride or molten chlorides to remove the calcium and magnesium, and cast as lead-bismuth bullion.

The bismuth bullion or crude bismuth is melted and the contained arsenic, tellurium, copper, silver, and gold are removed by addition of suitable fluxes and by temperature control. The final refining of the bismuth is accomplished by treatment with chloride to remove zinc and lead as a dross. The bismuth metal is covered with molten caustic soda and cast as refined bismuth. This method of refining results in a bismuth metal of a purity up to 99.999 percent.

USES

Approximately 60 percent of the bismuth consumed in the United States is used in the manufacture of alloys. The most useful of these are the so-called fusible alloys. Bismuth is the chief ingredient, varying in quantity from 40 to 99 percent. Fusible alloys are used in a number of safety devices such as plugs for compressed-gas cylinders, automatic sprinkler systems, fire-door releases, electrical fuses, and ammunition solders. Other uses of low-melting-point alloys are in dental work, tool-tempering baths, fabric-dyeing baths, and pattern-making and tool-anchoring devices.

Bismuth is used in increasing quantities to improve the machinability of aluminum alloys and malleable irons and steels. Addition of small quantities increases the cutting qualities of the alloy without great sacrifice of important properties such as strength, toughness, and corrosion resistance. Extended life of the cutting tools and decreased cutting time greatly lowers unit cost of machined pieces produced from the bismuth-doped alloys.

In addition to their low fusibility, bismuth alloys possess several other distinct and useful properties. Like water, bismuth expands on passage from the molten to the solid state. This characteristic is imparted to many of the metal's alloys. In the bismuth-lead-tin system, structural changes after solidification cause further volume growth. Proper blend of the constituents yields alloys in which expansion may offset thermal contraction, yielding a casting of the precise dimensions of the mold.

Precision duplication also is fostered by the low surface tension of bismuth-alloy melts. High fluidity permits complete filling of the mold, even in molds having complex reentries.

The other major use of bismuth is as an ingredient in the manufacture of a wide variety of medicinal and industrial compounds. Some important bismuth compounds are the trioxide, hydroxide, trichloride, subcarbonate, subchloride, subiodide, nitrate, citrate, subsalicylate subgallate, and sulfocarbonate. Various compounds, salts, and mixtures of these are used for indigestion remedies, antacids, burn and wound dressings, antisyphilitics, dusting power, and cosmetics.

Insoluble salts of bismuth are given to patients before X-ray examination of the digestive tract. Bismuth trichloride is claimed to render some waterproofing materials, such as tar, creosote, and nondrying oils, less flammable. Bismuth trioxide has been used to a limited extent in vitreous enamels, porcelain, and glass, chiefly as a flux to increase the fusibility of coloring oxides or compounds. In these uses it resembles lead oxides but has the advantage of being nonpoisonous.

Experimental work consumes a significant amount of bismuth in the continuing scientific search. New applications together with other undefined uses represent 1.5 percent of the total annual consumption.

BYPRODUCTS AND COPRODUCTS

All bismuth produced in the United States is a byproduct of mining, smelting, and refining of other metals and ores, predominantly lead and copper, containing relatively small quantities of bismuth. Metallurgical affinity of bismuth for lead and the economics of byproduct processing cause the source material to collect and be extracted at primary lead refineries.

ALTERNATE MATERIALS

Despite many possible substitutes, bismuth holds a relatively stable position in most of its areas of use. Pharmaceuticals are the most vulnerable. Kaolin performs functions similar to those of many bismuth preparations. Antibiotics have substituted for others. Special plastics, resins, and alloys of other metals may substitute for bismuth alloys that are valued for precision casting and low fusibility. However, under present technologic and economic conditions bismuth remains the favored commodity.

SECONDARY SOURCES AND RECOVERY

Although many of the fusible alloys are reused by the original purchaser, traffic in bismuth scrap is small. That which does enter commerce reenters fusible alloys, bypassing the metal production stage. Availability of scrap limits secondary bismuth output.

Spent industrial chemicals and overaged pharmaceuticals are treated to recover the metal content. Fusible alloys such as those used in bending airframes and in anchoring tools are remelted and used repeatedly. Although secondary processing is insignificant, there is a large demand for scrap.

RESERVES

Because ultimate recovery of bismuth generally is as a byproduct of lead smelting, estimation of the recoverable resource is a function of the relationship of bismuth production and smelter production of lead projected on the estimated lead resources. The world bismuth resource is thus inferred to be at least 112 million pounds of recoverable metal, of which the United States would contribute 10 million pounds.

The principal foreign sources in order of importance are the copper, lead, and silver deposits of Peru, the lead deposits of Mexico, the tin and tungsten deposits of Bolivia, the lead-zinc ores of western Canada, and the tungsten ores of the Republic of Korea. The principal domestic sources are the lead-silver ores of Utah and Colorado and the copper-lead-zinc ores of Montana, Utah, Nevada, Arizona, Idaho, and New Mexico. Some gold ores of Idaho, Montana, Nevada, Alaska, Colorado, and other States contain minor quantities of bismuth, but it is not ordinarily recovered.

SOURCES OF STATISTICAL INFORMATION

The Bureau of Mines collects and tabulates data on production, consumption, and stocks of refined bismuth on a quarterly schedule. The Bureau also collects data informally on imports of bismuth-containing intermediate smelter products that are used directly by the consuming industry or that serve as source material for domestically refined bismuth production. There are numerous foreign publications that give fragmental statistics on production and consumption. Information on imports of refined bismuth is obtained from the U.S. Department of Commerce, Bureau of the Census. Exports of bismuth metal and alloys are also reported by the Bureau of the Census, but data are in terms of gross weight rather than contained bismuth.

The statistical sources for bismuth metal are adequate for the purposes to which the data are applied. Data on imports of bismuth alloys and bismuth-lead bars are, however, inadequate to provide a comprehensive picture of the industry.

PRODUCTION, CONSUMPTION, AND TRADE

Domestic production of refined bismuth is derived from intermediate smelter products of high-bismuth content collected in smelting of domestic and foreign ores and recovered at lead refineries. Production is confined to three

companies: American Smelting and Refining Co., United States Smelting Lead Refinery, Inc., and United Refining & Smelting Co. Quantitive production data supplied to Government are company confidential and therefore not available for publication. World production of bismuth by countries is shown in table 1.

World consumption statistics are not available by countries but the rising demand reflected in statistics of the United States undoubtedly applies to other industrial countries of the world and approximate the expanding supply availability. The United States is by far the largest consumer and in 1963 required about one-third of the world production. Salient statistics of bismuth in the United States are presented in table 2 and uses of bismuth in the United States is shown in table 3.

TABLE 1.—*World production of bismuth, by countries* [1] [2]

[Pounds]

TABLE 3.—*Bismuth metal consumed in the United States, by uses*

[Pounds]

Use	1962	1963	Use	1962	1963
Fusible alloys	[1] 795,588	763,862	Experimental uses	5,212	6,433
Other alloys	442,040	572,543	Other uses	21,559	23,817
Pharmaceuticals [2]	645,149	808,383	Total	1,909,548	2,175,038

[1] Includes 159,188 pounds of bismuth contained in bismuth-lead bullion used directly in the production of an end product in 1962 and 168,137 pounds in 1963.
[2] Includes industrial and laboratory chemicals.

Imports form a large segment of the United States bismuth supply. In 1959–63, yearly receipts of refined bismuth from foreign countries averaged 872,000 pounds and furnished over 50 percent of the total metal available for consumption. Peru supplied 63 percent, Mexico 20 percent, Canada 9 percent, and Yugoslavia 5 percent, the remaining 3 percent was shipped from many other countries in Europe and Asia.

Metal imports are augmented by substantial quantities of bismuth that enter the United States as minor constituents of base bullion, in ores other than bismuth, and as impure bismuth-lead bars. The economically recoverable bismuth content of the ores and bullion enters the market as domestically refined bismuth. Most of the bismuth-lead bars, however, are consumed directly in alloy fabrication. Statistics relating to this category of imported bismuth are not formally collected by the Government. In some years estimates have been about 0.5 million pounds.

The United States is not traditionally an exporter of bismuth, but in years of slack industrial demand the rather inflexible nature of domestic production makes overseas sales desirable. The European market customarily is willing to absorb U.S. surpluses. Because economic cycles in Europe are often out of phase with those in the United States, domestic bismuth users occasionally absorb European surpluses.

Tariff on refined bismuth metal is 1⅞ percent ad valorem, effective since October 7, 1951, pursuant to concessions under the General Agreements on Tariffs and Trade. Chemical compounds, mixtures, and salts of bismuth are dutiable at 28 percent ad valorem, a rate that has applied since August 31, 1963. Bismuth ores and concentrates are entered duty free. The bismuth content of intermediate smelter products, such as base bullion, is dutiable on base metal content. Industrial alloys are dutiable at 18 percent ad valorem.

STRATEGIC CONSIDERATIONS

The degree to which the United States depends on foreign supply and the importance of precision castings and low-melting point alloys qualify bismuth as a strategic material. The United States holds stocks of the metal in the national and supplementary stockpiles to meet presently anticipated emergency requirements.

Approximately half of the U.S. yearly requirements of refined bismuth is imported. In addition, it is estimated that half of the domestic output of refined bismuth is derived from source materials of foreign origin. A substantial quantity of the Nation's bismuth needs enters the country in forms that bypass the metal stage, entering directly into alloy fabrication. It is estimated that 90 percent of the U.S. annual bismuth requirements originate abroad.

GOVERNMENT PROGRAMS

Under various congressional authorizations in times of national need the Government has stockpiled bismuth, controlled prices, allocated supply, and explored for domestic ore deposits. Exploration assistance is presently available under the program of the Office of Minerals Exploration with Government participation limited to 50 percent of the approved cost.

Under authority of the Stock Pile Act of 1946 and supplemental legislation the Government maintains an inventory of refined bismuth sufficient to meet emergency military needs. On June 30, 1964, inventories of refined bismuth totaled 3,835,000 pounds, of which 1,306,000 was in the national (strategic) stockpile, 23,000 pounds in Defense Production Act stocks, and 2,506,000 pounds in the supplemental stockpile. The total in the stockpile represented 106 percent of the presently anticipated emergency requirements.

In accordance with the Agricultural Trade Development and Assistance Act, the Commodity Credit Corporation may barter domestic surplus farm products for foreign bismuth metal.

PRICES

At the beginning of 1939, the New York price for refined bismuth metal was $1 per pound. Late in 1939 the price advanced to $1.25 per pound, where it remained until July 19, 1946. From that date until September 4, 1950, the average price was $1.95 a pound. On September 5, 1950, the price advanced to $2.25 a pound, in ton lots, where it remained until July 10, 1964, when it rose to $2.35.

TAXES

Depletion allowance for domestic producers of bismuth is 23 percent, and for U.S. producers with production in foreign countries, 15 percent.

TRANSPORTATION

Transportation costs are not a significant factor in the nationwide use of bismuth metal or alloys. Bismuth is sold in 6-, 10-, 22-, and 25-pound bars, the wholesale lot being 2,000 pounds. Bismuth bars are packed in cartons or wooden boxes protected with steel strappings. Wedges often are placed between the bars to prevent damage or breakage.

RESEARCH

The fundamentals of bismuth have been extensively studied and experimental research has developed a wide variety of industrial applications. The requirements of nuclear and astronautic developments offer a real incentive for scientific research on the potentialities of bismuth.

Research conducted by producers is primarily concerned with development and expansion of industrial markets for bismuth. Many broad industrial applications are attributed to basic experimental work sponsored by producers to exploit the unique properties and performance of the metal.

Consumers' research is more specialized, being confined to experimentation and development of special-purpose applications. Recent research concerned with thermoelectric energy conversion, using bismuth in combination with other junction materials, and with use of liquid metal cathodes has been promising. Nuclear uses are being investigated both as coolants and as a thermal neutron absorbant.

The Bureau of Mines has recently conducted research and published data on high-temperature heat, energy, and entropies of bismuth metal and bismuth compounds (*4, 7*).

OUTLOOK

The unusual and versatile properties of bismuth will continue to attract a comparatively large industrial research effort with a real possibility that substantial contributions will be made toward developing industrially important new technologic devices, methods, and products. Prospective new uses in thermoelectric elements and in chemicals are of major interest.

While the phenomenal rate of gain in consumption registered in 1962–63 is not expected to continue, a long-term growth potential of 3 percent annually, along with expected industrial growth, will require an estimated 2.5 million pounds of new metal supply for the United States by 1970.

The byproduct relationship of bismuth to production of other metals, as well as the relatively small quantity of bismuth recovered in relation to the host metals, imposes limits to which output can be expanded to meet increased demand. The currently improved outlook for host metal production and the presently indicated world overproduction capability predicate, however, an adequate supply to meet demand at a relatively stable price.

The supply-demand base for bismuth, measured in millions of pounds, does not provide the supply capability to meet rapid rise in demand resulting from a radically new and sizable use. Displacement of present market outlets and attendant price rises would necessarily follow, alleviated only to a small extent by high-cost bismuth ore production.

PROBLEMS

The primary commodity problem associated with bismuth is the dependence on foreign sources for the bismuth required to meet current and future industrial requirements.

Since the present supply is closely linked to and limited by resources and production of lead and copper, bismuth supply varies according to the demand for those metals rather than according to the independent requirements of bismuth. The relatively limited and inflexible supply thus restricts consideration of the useful and distinctive properties of bismuth for applications requiring substantial quantities.

Supply is vulnerable, especially in the strategic and mobilization areas, because of the lack of domestic bismuth deposits and base metal ores of high bismuth content, dependence of domestic refinery production on the bismuth content of imported base-metal ores and intermediate smelter products, and concentration of refinery capacity.

Inadequate information relative to several facets of the bismuth industry has impeded understanding of the supply-demand situation. The lack of information on the various components of domestic bismuth refinery production limits understanding of domestic supply potential. Basic knowledge of domestic source materials and contributing domestic mine sources is essential toward development of a program to improve the domestic resource base.

Although bismuth has been favored with substantial scientific attention and research development, problems exist in the application of bismuth in the nuclear and thermoelectric fields.

BITUMINOUS COAL

By Staff, Division of Bituminous Coal

In establishing high standards of living and assuring continuity of industrial progress, energy has played a leading role. Of all the fossil-fuel sources of energy, coal is the most abundant.

Over millions of years, decaying plant material in swampy areas was transformed into various ranks of coal which are not sharply divided but overlap because the starting material is similar for all coals. In order of increasing rank, coals are classified as lignitic, subbituminous, bituminous, and anthracitic. Coal, like wood and peat, contains carbon, hydrogen, oxygen, nitrogen, sulfur, and other elements in small quantities.

The United States has one-third of the world reserve of coal. Nearly 80 percent of the reserve, on the basis of heating value per pound, is bituminous and subbituminous. These ranks of coal are widely distributed over the United States.

Coal is extracted from the earth by underground and strip mining. Modern, mechanized mining has achieved higher productivity and efficiency, greater safety for miners, and a minimum of hard labor. After mining, coal is mechanically prepared to remove impurities and crushed to sizes suitable for its ultimate use. It may be burned domestically or used to generate power, gasified for industrial or home uses, or coked for metallurgical purposes. The by-products from coking—gas, tar, and light oils—can be used as such or processed further to serve as raw materials for the chemical industry.

The bituminous coal and lignite industry, widely dispersed over the Nation, reached its peak production of over 630 million tons in 1947. Between that time and 1963, production dropped 172 million tons per year, the number of mines decreased from 8,700 to 7,940, and the number of men employed dropped from more than 440,000 (in 1948) to 142,000. The decline in production has resulted primarily from the competition of oil and natural gas in the energy market. As a result of our steadily growing population and increasing demands for the thermal generation of electric power, however, there are great expectations for substantially increased coal production in the future, although the buildup probably will be on a gradual basis as competition from oil and natural gas continues and that from nuclear energy for power generation increases. Also, as a result of technological research, it is expected that important new uses for coal will be developed, including the conversion to liquid and gaseous fuels.

BACKGROUND

Coal is the primary energy source upon which the Nation's phenomenal industrial and economic growth has been based. The coal industry grew rapidly and steadily from its early beginning, and reached the 100 million ton production level in the 1880's.

At the turn of the century, there were over 3,000 bituminous coal and lignite mines, employing over 300,000 workers in widely dispersed areas of the country. Production exceeded 212 million tons and was valued at $221 million. In 1918, when bituminous coal accounted for 70 percent of the Nation's total energy production, output reached a peak of 579 million tons. Employment reached 705,000 in 1923, with over 9,000 mines in operation. Following the low levels of production during the depression of the 1930's (when output plummeted to only 310 million tons in 1932 and the number of mines dropped to 5,400), and after more than a decade of operating at a deficit, the industry produced its alltime record of 631 million tons in the postwar reconversion year of 1947, with only 419,000 workers. Ap-

proximately 43 million tons, however, was for overseas export (at that time an abnormal market for coal), primarily to assist in the rehabilitation of Europe. This increase in coal production was indicative of the new and tremendous need for energy. For, although total coal production had increased, its actual share of the energy market declined, with oil and natural gas supplying ever-increasing quantities of fuel to the Nation's expanding energy market.

By 1942 coal contributed 52 percent to total energy production. By 1958 coal's share had declined further and was only 28 percent. Since the peak year of 1947, production has been sporadic. Output was only 392 million tons in 1954, 500 million tons in 1956, 410 million tons in 1958, and 459 million tons in 1963. For the past decade the total value of coal produced has averaged over $2 billion annually. The average value per ton of bituminous coal reached its highest level of $5.08 in 1957; for the 6 years since, average value declined each year and in 1963 amounted to $4.39 per ton, an average yearly decline of 11.5 cents per ton, notwithstanding substantial and continuing increases in wages and in costs of material and supplies. The ability of the coal industry to avert spiraling prices and in some cases actually to decrease prices, so as to hold much of its energy market, has been due to its phenomenal record of increased productivity and efficiency of operation resulting from mechanization, which also has contributed substantially to the drop in employment in the industry. Productivity climbed from 5 tons per man per day in 1930 to 11 tons in 1958 and to nearly 16 tons in 1963, as mechanical loading increased from 10 percent of underground production to 86 percent in 1960, and surface or strip mining increased from 4 percent to 31 percent in the same period. Productivity in the bituminous coal industry of the United States is approximately eight times that of the other coal mining nations of the world.

Coal's decline in some markets has been rapid and drastic. The railroad locomotive fuel market has swung to diesel oil, with coal supplies dropping from 132 million tons in 1944 to only about 1.5 million tons in 1963. There also have been significant declines in retail deliveries of bituminous coal and lignite to other than the leading consuming groups and in shipments to miscellaneous manufacturing and mining industries.

While the annual market for coking coal for the iron and steel industry has been declining—averaging 104 million tons per year during the 5-year period ending 1957 and 77 million tons per year during the 5-year period ending 1963—and is expected to continue around the lower level, the brightest spot for coal has been the tremendous demand for steam generation of electricity to meet the phenomenally increasing requirements for electric power throughout the Nation. Bituminous coal and lignite consumption at electric-power utilities increased from 27 million tons in 1933 to 209 million tons in 1963. The upward trend in coal demand by electric power utilities is expected to continue at such an accelerated rate that some estimates of coal requirements for this purpose within the next 15 years range close to 800 million tons per year—more than three times the amount of coal used now.

Because its great bulk requires heavy transportation equipment and facilities, coal historically has been of great importance to the heavy transportation industries. As a result, much of the economic health of these industries, particularly the railroads and, to a substantial degree, water and truck shippers, depends on coal. The economic position of manufacturers of machinery used in mining also is closely allied to trends in the coal industry. In addition, hundreds of communities throughout the country are wholly or substantially dependent on coal mining activity for their economic well-being. The shifting pattern of energy availabilities and consumption in the United States, and the extent to which coal will approach its earlier significance in the energy market, are of critical interest to these components of the Nation's economy, as well as to the coal industry.

SIZE, ORGANIZATION, AND GEOGRAPHIC DISTRIBUTION OF INDUSTRY

The bituminous coal industry ranks high among the major mining industries of the United States in capital value, in value of annual output, and in number of employees. Moreover, production is well distributed throughout the country from the Appalachian region to the Rocky Mountains. In 1963 the value of bituminous coal and lignite production, f.o.b. mines, amounted to over $2 billion. Nearly 8,000 mines employed more than 141,000 men directly in production.

The organization of the industry follows the familiar lines of private enterprise, being highly competitive, with the largest single producer accounting for less than 9 percent of total production. In number, the industry is comprised principally of single-mine producing companies. Larger companies, however, operate several mines, and there is a growing trend toward consolidation in order to effect greater economies of operation and administration. These larger organizations represent the major proportion of production; in 1963, only 9 per-

cent of the mines accounted for 78 percent of total coal production. A sizable portion of total production, 14 percent in 1963, is by "captive" mines, most of which are affiliated with the steel industry and a much smaller portion with the electric utility industry.

A national trade association for the industry, many local associations, an export association, and several producers' associations for wage bargaining purposes exist. Except in the field of safety, in times of national defense emergencies, and in the possible application of such measures as the Taft-Hartley Act and the Sherman antitrust laws, there is no direct Government control of the industry in the sense of regulated production, marketing, or prices as exists in some coal-producing countries.

Over the years there have been wide variations in production in the several States. For instance, total production in the United States reached its peak in 1947 (see table 1). Maryland, Arkansas, and Michigan all reached their maximum production in 1907. Nine States including Illinois and Pennsylvania, reached their peak during World War I. In contrast, Kentucky, West Virginia, and Utah attained their maximum output in 1947, and Virginia was largest in 1963. Ranked in terms of production in 1963, West Virginia was first followed by Kentucky, Pennsylvania, and Illinois, in the order listed. Only six States have produced over 1 billion tons from earliest records to the end of 1963: Pennsylvania (8.5 billion), West Virginia (6.8), Illinois (3.8), Kentucky (2.9), Ohio (2.2), and Indiana (1.2).

There are wide differences among regions in production, number of mines, uses of coal, average value per ton, men working, days worked, and output per man-day. Most of these differences are explainable in such terms as extent of mechanization, quality of product transportation, and market demands.

TABLE 1.—*Maximum and total production of bituminous coal and lignite in the United States by States*

[Thousand short tons]

State	Maximum production		Total production from earliest record to end of 1963
	Year	Quantity	
Alabama	1926	21,001	997,799
Arkansas	1907	2,670	99,539
Colorado	1917	12,483	520,867
Illinois	1918	89,291	3,797,396
Indiana	1918	30,679	1,210,616
Iowa	1917	8,966	355,845
Kansas	1918	7,562	282,859
Kentucky	1947	84,241	2,921,184
Maryland	1907	5,533	269,699
Missouri	1917	5,671	298,291
Montana	1944	4,844	172,127
New Mexico	1918	4,023	128,437
North Dakota	1950	3,261	[1] 103,500
Ohio	1920	45,878	2,194,711
Oklahoma	1920	4,849	183,903
Pennsylvania	1918	178,551	8,493,723
Tennessee	1956	8,848	412,623
Utah	1947	7,429	276,684
Virginia	1963	30,531	906,122
Washington	1918	4,082	149,114
West Virginia	1947	176,157	6,835,126
Wyoming	1945	9,847	411,852
Other States [2]			188,052
United States	1947	630,624	31,210,069

[1] Excludes production in 1954 to avoid disclosing individual company confidential data. Included in other States.
[2] Includes Alaska, Arizona, California, Georgia, Idaho, Michigan, North Carolina, Oregon, South Dakota, Texas, and North Dakota in 1954 only.

DEFINITION OF TERMS, GRADES, AND SPECIFICATIONS

Classifications of coal are based on their nature and chemical composition, and these in turn depend on the kind of original plant material, its partial decay in peat swamps, and subsequent metamorphism by geological processes throughout the ages. Various national classification systems have been developed to describe the characteristics of domestic coals. Although many of these systems had features in common, the different terms and standards used to describe similar or identical coals have caused confusion in evaluating coals shipped in international trade. In 1949 the Coal Committee of the Economic Committee of the Economic Commission for Europe established a Classification Working Party to develop an international system for classifying coal. Every major European coal producing or consuming country and the United States participated in this work, which resulted in developing a system for the international classification of hard coals by type and beginning work to develop a similar system for lower rank coals.

Coal, like wood and peat, contains carbon, hydrogen, oxygen, nitrogen, sulfur, and other elements in small quantities. The proportions in which the major elements are present differ greatly in different kinds of coal, and the chemistry of coal is quite complicated. For practical purposes, however, coal is analyzed by proximate analysis or sometimes by a more complete test—ultimate analysis—to determine the amounts of chemical elements.

The *proximate analysis* of coal involves the determination of four constituents: (1) water, called moisture; (2) mineral impurity, called ash, left when the coal is completely burned; (3) volatile matter, consisting of gases or vapors driven out when coal is heated to certain temperatures; and (4) fixed carbon, the solid or cokelike residue that burns at higher temperatures after volatile matter has been driven off. *Ultimate analysis* involves the determination of carbon and hydrogen as found in the gaseous products of combustion, the determination of sulfur, nitrogen, and ash in the material as a

whole, and the estimation of oxygen by difference.

Moisture, sulfur, and ash are the undesirable ingredients of coal. Volatile matter and fixed carbon are the most important contributors to the energy produced when coal is burned; and producing energy in the form of heat is the largest use of coal.

To find the heating value of a particular coal, a sample is weighed precisely and burned in a calorimeter, i.e., a bomb filled with compressed oxygen and immersed in a measured quantity of water at a known temperature. The heat released during the combustion of the coal sample is transferred to the calorimeter, and the rise in temperature is observed. The heating value of coal is then calculated, and is generally expressed in British thermal units (Btu) per pound. One Btu is the amount of heat needed to raise the temperature of 1 pound of water 1° F.

The rank or degree of coalification of the higher rank coals depends on the amount of fixed carbon in the coal, as indicated by proximate analysis. For the lower rank coals, heating value and caking and weathering properties are used to define rank. The rank of coal increases as the amount of fixed carbon increases and the amount of moisture and volatile matter decrease. There is great variation in the composition of coals, as can be seen from the following analyses, on an ash-free basis, of a typical lignite, the lowest rank of coal, and an anthracite, the highest:

	Lignite (percent)	*Anthracite (percent)*
Fixed carbon	33	92
Volatile matter	26	5
Moisture	41	3
Total	100	100

Table 2 lists the ranks of coal; a general description of these coals is given below. *Lignite* (including brown coal) ranges in appearance from brown to black. It yields a brown powder when ground or when rubbed over a rough, white surface. American lignite as mined contains 30 to 45 percent moisture. When exposed to air it loses moisture and crumbles to slack. Although there are large deposits of lignite in the United States, its production is not yet important nationally, partly because it is far from major markets. Greater precautions must be taken to store it satisfactorily, and its heating value is lower than bituminous coal, making the shipment of unprocessed lignite for long distances uneconomic.

Subbituminous coal is black; as mined, it looks much like the bituminous coal commonly seen in coal yards. It contains 15 to 30 percent moisture. The range of heating values of subbituminous A coal is the same as that of high-volatile C bituminous coal. Subbituminous coal is entirely noncoking. Like lignite, it weathers upon exposure to air and is more difficult to store than are the higher rank coals, and it is used principally in the areas where it is mined.

Bituminous coal is the most abundant and widespread rank of coal in the United States. It is the coal used most commonly for industrial, power, and space-heating purposes. Bituminous coal may be either coking or noncoking. This property is not based on the rank of the coal but rather on whether it will produce a coke when processed in a coke oven. Nearly all eastern bituminous coals have caking properties, but many of the western bituminous coals are noncoking and are free burning.

Both *coking* and *caking coals* soften and flow when they become almost hot enough to take fire. As they are heated further, some degradation occurs, and volatile matter escapes as gas and vapors. When coking coals are heated red hot in a sealed oven where there is little or no air, a dull gray, porous mass—coke—remains after most volatile liquids and gases have been driven off. Because coke consists largely of fixed carbon, coking is often called carbonization. Under similar conditions, caking coals agglomerate, yielding a product not acceptable for coke from a strength standpoint.

Noncoking bituminous coal may look like coking coal, and its composition may be similar, but it burns freely without pronounced agglomeration. Instead of a porous mass, it leaves a char of powdery residue. Noncoking and coking bituminous coals may be used interchangeably as a fuel for power plants, railroads, and heating and cooking. For some purposes, however, coking coals are required, the principal one being the manufacture of coke for smelting iron ore in blast furnaces. Noncoking coals are used for cement and tile manufacture.

Most bituminous coals appear black and lustrous in the pile; but close inspection shows a banded structure with alternate layers of bright, glossy coal and dull, grayish black coal. In some coals this dull material predominates, and these are known in the trade as *splint coals*. In thin sections, red and yellow areas representing different constituents can be observed. Finely powdered coal generally appears brown.

Anthracite, sometimes called *hard coal*, usually has a brilliant luster and uniform texture. Anthracite has a higher percentage of fixed carbon and a lower percentage of volatile matter than the lower rank coals. It burns slowly, with a pale-blue flame free from smoke. Most anthracite has a somewhat lower heating value than the highest grade bituminous coals, but its lack of soot and the fact that it will burn

TABLE 2.—*A.S.T.M. classification of coals by rank*[1]

[F.C.=fixed carbon; V.M.=volatile matter; Btu=British thermal units]

Class	Group	Limits of fixed carbon or Btu, mineral-matter-free basis	Requisite physical properties
I. Anthracitic	1. Meta-anthracite	Dry F.C., 98 percent or more (dry V.M., 2 percent or less).	Nonagglomerating.[2]
	2. Anthracite	Dry F.C., 92 percent or more and less than 98 percent (dry V.M., 8 percent or less and more than 2 percent).	
	3. Semianthracite	Dry F.C., 86 percent or more and less than 92 percent (dry V.M., 14 percent or less and more than 8 percent).	
II. Bituminous[3]	1. Low-volatile bituminous coal	Dry F.C., 78 percent or more and less than 86 percent (dry V.M., 22 percent or less and more than 14 percent).	
	2. Medium-volatile bituminous coal.	Dry F.C., 69 percent or more and less than 78 percent (dry V.M., 31 percent or less and more than 22 percent).	
	3. High-volatile A bituminous coal.	Dry F.C., less than 69 percent (dry V.M., more than 31 percent); and moist Btu,[4] 14,000[5] or more.	
	4. High-volatile B bituminous coal.	Moist Btu,[4] 13,000 or more and less than 14,000.[5]	
	5. High-volatile C bituminous coal.	Moist Btu,[4] 11,000 or more and less than 13,000.[5]	Either agglomerating or nonweathering.[6]
III. Subbituminous	1. Subbituminous A coal	----do----	Both weathering and nonagglomerating.
	2. Subbituminous B coal	Moist Btu,[4] 9,500 or more and less than 11,000.[5]	
	3. Subbituminous C coal	Moist Btu,[4] 8,300 or more and less than 9,500.[5]	
IV. Lignitic	1. Lignite	Moist Btu,[4] less than 8,300[5]	Consolidated.
	2. Brown coal	----do----	Unconsolidated.

[1] This classification does not include a few coals that have unusual physical and chemical properties and that come within the limits of fixed carbon or Btu of the high-volatile bituminous and subbituminous ranks. All of these coals either contain less than 48 percent dry, mineral-matter-free fixed carbon or have more than 15,500 moist, mineral-matter-free Btu.

[2] If agglomerating, classify in low-volatile group of the bituminous class.

[3] It is recognized that there may be noncaking varieties in each group of the bituminous class.

[4] Moist Btu refers to coal containing its natural bed moisture but not including visible water on the surface of the coal.

[5] Coals having 69 percent or more fixed carbon on the dry, mineral-matter-free basis shall be classified according to fixed carbon regardless of Btu.

[6] There are three varieties of coal in the high-volatile C bituminous group, namely (1) agglomerating and nonweathering; (2) agglomerating and weathering; (3) nonagglomerating and nonweathering.

longer without attention make anthracite a more desirable domestic fuel than bituminous coal.

There are four types of bituminous and subbituminous coal—common-banded, splint, cannel, and boghead.

Common-banded coal includes most of the coals. It is composed of both anthraxylon (bright bands) and attritus (dull bands) in varying proportions and has a bright luster. *Anthraxylon*, meaning "coal from wood," is the name given to the glossy, jet-black bands in a lump of coal. These bands were formed from the woody parts of plants—their stems or trunks, limbs, and branches. *Attritus* refers to the finely divided matter of which the dull bands of coal are largely composed. This material is a mixture of plant debris consisting of the more resistant residues of various parts and organs of plants, such as cell walls, leaf tissue, spore coatings, pollen, and resin particles.

Splint coals are composed almost wholly of attritus, with only a little anthraxylon. The coal is dull, grayish black, hard, and tough. When mined, it breaks into block lumps; because of this characteristic, it is called *block coal* in some mining regions. Splint coal is good fuel for steam power plants. The name splint coal is probably derived from the fact that large lumps splinter on heating. Used in blends with banded coals, it may improve coke structure.

Cannel coals are also made up almost entirely of attritus. They are often rich in spores, the reproductive organs of the lower plants that do not produce seeds. This coal usually contains a high percentage of volatile matter and burns with a long, yellow flame. It used to be called *candle coal* because of the appearance of the flame and because it can often be lighted with a match. Cannel coal differs from splint coal in that it is more easily ignited, and retains its shape in burning. Cannel coal is used chiefly as a fireplace fuel; it was a desirable coal for making illuminating gas in an earlier era. It usually occurs in small lenses or deposits in beds of other coals and may be separated from them during mining.

Boghead coal is a variety of bituminous or subbituminous coal that looks and burns much like cannel coal. It is made up largely of the remains of algae—water plants that form the greenish or brownish scum often seen on freshwater ponds and reservoirs in summer and fall. It is rich in volatile matter. When distilled, it yields a great deal of gas, tar, and oil. Like cannel coal, it is usually found in small deposits or lenses.

TECHNOLOGY

Coal has been used for more than 2,000 years. As a result of technologic achievements both within and outside of the coal industry, and the steadily increasing demands for fuel, coal has found new markets, and new applications. These, in turn, have required the development of new or improved technology in mining and preparation. During the last 20 years, mining has been mechanized to an increasing extent,

and preparation techniques are being modified to solve the problems associated with mechanization, and with changing patterns of utilization. These aspects are discussed in greater detail below.

Geology

Although coal is commonly thought of as a mineral, it differs from the broad definition of minerals that are natural inorganic elements or compounds, having a definite chemical composition. Coal is of organic origin, formed from the remains of living things—aquatic and land plants including trees, shrubs, herbs, vines, and ferns—that grew millions of years ago, during periods of tropical or mild, humid climates. Some types of plants appear to have contributed more importantly than others to the original deposits. The physical and chemical changes which the vegetation underwent are primarily responsible for the type of coal produced. Many of the plant forms found in coals that are more than 200 million years old are similar to species commonly known today.

The heavy growth of trees, ferns, and other plants in swamps and bogs that grew and fell century after century, accumulating in situ, was buried to a gradually increasing depth each year by new accumulations. These plant remains changed gradually to peat, just as decaying vegetable matter is doing today in the Dismal Swamp of Virginia and North Carolina and in smaller swamps and bogs in many areas.

Peat is the first product when organic matter begins to change to coal. In a block of peat one can often see, with the naked eye, woody fragments of stems, roots, and bark. As peat is buried, it is cut off from the oxygen in air, and rapid decay of its organic matter is prevented by slowing bacterial action. The weight of more vegetation falling on the peat helps to compress and solidify it, as does the weight of water when the deposit sinks below a lake or sea, as has often happened. Sometimes mineral sediments have settled from muddy flood waters while vegetable matter was accumulating and formed partings or layers of shale in the resultant coal bed. At the end of coal-forming periods, swamps remained flooded for a long time, and earthy sediments were deposited in thick beds over the peat, further compressing it and starting coalification, the coalmaking process.

Coalification is extremely slow when it depends mainly upon pressure generated by overlying rock. For this reason, many coal deposits are still of low rank, that is, in an early stage of coalification, although they have been buried millions of years. A few deposits, however, are situated where profound movements of the earth's crust occurred during periods of mountain building. This rock movement generated heat, pressure, and shearing forces producing high-rank coals, such as medium- and low-volatile bituminous coal and anthracite.

The coalfields of the United States cover roughly 400,000 square miles or approximately one-ninth of the total area of the United States. According to the latest estimate, the total recoverable reserves of coal are 1,735 times the 1963 annual production (on a ton-for-ton basis and 1,380 times on a Btu basis). The distribution of these reserves and other related information are discussed in later sections of this chapter.

Mining

In America, coal first was recovered from coal outcrops on the hill and mountain slopes with picks and shovels and simple methods of conveying. However, as the more accessible outcrops were depleted, it was necessary to follow the coal measures into the earth. The coal mining industry then was faced with new and complex problems such as ample transportation facilities, mine ventilation, and roof control. Solving these problems became the primary objective of improving coal mining technology. Today, these objectives have become: (1) high productivity in terms of tons per man-shift, (2) maximum safety for the miners and (3) minimum need for hard labor.

Methods for obtaining safety in mining have undergone much study and development in recent years. The early method of blasting coal with black powder has been replaced with safer explosives—permissible explosives which have a shorter flame duration. Also, some mines now use compressed carbon dioxide or air for breaking the coal rather than explosives. To prevent a mine roof from caving, props made of wood or steel and yielding steel arches may be used. In the last 12 years the practice of roof bolting has grown phenomenally. Expansion bolts are wedged into holes drilled in the roof to bond the overlying rock and slate strata together thus forming a strong span.

Ventilation in underground mining must be provided, not only to supply fresh air to the worker but to remove explosive gases such as methane trapped in the coalbed and released during mining. Methane concentration must be checked at frequent intervals and, when necessary, ventilation must be increased or men withdrawn from the mine until the explosive danger has been removed. Another hazard of

equal importance is introduced by coal dust, which may form a highly explosive mixture with air. Frequent removal of such dust, washing it down with water spray, and diluting it with nonflammable rock dust help to solve this problem.

Constant vigilance and inspection, testing of equipment for use underground, and adoption of improved practices have greatly lowered the number of accidents in mines. The Bureau of Mines program of training mine inspectors and certifying explosives, shot-firing units, blasting devices, safety lamps, and electrical equipment has contributed greatly to increasing safety in underground mines.

Strip Mining

When coal occurs near the surface, strip or open-pit mining may be more economical. Where the coal deposit is thick, as at Kemmerer, Wyo., the open pit may be terraced down, as in the mining of massive copper ore bodies. In flat country, where the deposit is nearly horizontal and of normal thickness, the earthy cover (overburden) is removed with huge power shovels. The coal is then scooped up by smaller power shovels and loaded into trucks. Operations may follow the bed until the ratio of overburden to coal makes production uneconomic. Another form of strip mining—contour stripping—is used in hilly or rugged terrain where the outcrop runs around the hill or mountain. Again, cost factors determine the depth of cut and width of the strip.

The phenomenal growth of strip mining was made possible by developing large capacity shovels, trucks, and new explosives, such as ammonium nitrate, which is now very widely used for breaking overburden. Some shovels now are 140 cubic yards in bucket capacity. The earlier types of shovels (semicircular serving railroad-type shovels) were replaced by full-revolving shovels able to dig and dump in any direction. In turn, came crawler traction and development of large dragline excavators and Carryall scrapers. Steam and gasoline shovels have been decreasing while electric- and diesel-powered shovels have been increasing. Improvements have been made in power drills for shooting holes in overburden and in trucks for hauling the coal from strip pits to tipples or railroad ramps. Some of the trucks used are now 55 cubic yards in capacity.

Strip mining has a substantial advantage over underground mining: Output per man-shift in strip mines is more than twice as large as in underground mines, resulting in a lower cost and price per ton of strip coal. In 1963, the average value at the mine for underground coal was $4.82 per ton and for strip coal $3.57.

Auger Mining

One of the recent developments in soft-coal recovery is auger mining. Many strip mines, particularly in the rough terrain of the Appalachian region, gradually encounter overburden so thick that continued stripping becomes economically impracticable. These strip mines have vast areas of coal seams exposed along what is known as highwall. Auger mining employs a large auger as a cutting head and a tube and screw for transporting coal. The mechanism is unitized so that the coal-removing system is extensible as the cutter penetrates the coal measure. The auger is generally operated from an outcrop location. The labor force is small, and recoveries of about 60 to 65 percent of the coal are reported. After much experimentation, huge augers were designed to bore horizontally into the exposed solid seam of coal much as a carpenter's auger bores into wood. These augers, 16 to 52 inches in diameter, are mounted on movable frames and bore holes 100- to over 200-feet deep. The coal falls from the auger into a conveyor and is elevated into a truck. This type of mining is generally known as highwall auger mining.

Punch mining, another secondary method of recovering coal which would otherwise be lost, involves the use of either continuous or conventional types of mining equipment. In this type of mining, which follows regular underground and strip mining operations, coal is recovered by the application of underground mining techniques, e.g., the driving of short entries and rooms and recovering the small pillars on retreat. The mined coal is then transported by trucks and other equipment that are normally used in stripping operations.

Auger mining at soft-coal mines in the United States averaged 39 tons per man-day in 1963 compared with 29 tons at strip mines and 13 tons at underground mines. Under favorable operating conditions exceptionally high production is achieved, some mines averaging over 50 tons per man-day.

Underground Mining

Underground coal mines may be directly accessible by slope, drift, or vertical shafts (shaft mines). These terms derive from the manner of entry and of moving coal to the surface. Mining methods include room-and-pillar and longwall mining.

The prevailing mining system in the United States is the traditional room-and-pillar. In general, the entries into the coal measure serve as haulageways and fan out into the coalbed with side or cross entries from which the coal is removed to form rooms. Up to about 50 per-

cent of the coal is left to support the roof—usually slate or rock. To conserve resources and obtain maximum coal output, pillars are sometimes removed on the retreat.

For many years coal was drilled, blasted, and then manually loaded into cars for transportation to the tipple at the surface. Later, cutting machines were introduced for undercutting, overcutting, or making vertical cuts. Lateral cuts were often made for bench mining or keeping partings of slate separate from the coal.

In recent years coal mining has been highly mechanized, and loading and conveying are no longer manual. In fact, continuous mining machines have been developed that cut, load, and convey the coal to belt conveyors for transport to the outside. With the development of mechanization, the use of explosives has declined, and productivity has increased.

One type of continuous miner, mounted on rubber tires or crawler treads, has multiple cutters on a horizontal boom that make vertical cuts from floor to roof. Coal is mechanically swept to a chain conveyor and passed to the rear of the machine onto a shuttle car or a continuous conveyor.

Another type of continuous miner has several circular cutters that revolve vertically. The cuttings are thrown, by appropriate opposed directions of rotation (clockwise and counterclockwise) of the cutters, to the center of the machine front and are carried back on an integral conveyor.

These machines represent typical, fully mechanized machines used in room-and-pillar and modified room-and-pillar mining in the United States.

A coal planer or plow, designed for longwall mining, consists of a heavy base that extends the full length of the working face (300 to 600 feet long) and contains a coal conveyor. The plow is on the side of the base that faces the coal. It holds several cutter bits in a guide that point in opposite directions parallel to the coal face. In the guide is the pulling chain powered by electric motors at the extreme ends of the base. When power is applied, the planer rips off a thickness of about 4 inches of coal at the rate of 75 feet a minute. Coal falls onto the conveyor and is spilled continuously at the end of the machine onto other transporting systems. The long base is automatically kept tight against the face by air-operated piston jacks. Roof control in this case is temporary and effected by yielding props (50 tons per square inch) and collapsible cribs. The props are manually leapfrogged toward the receding working face. Behind the props the roof is allowed to break and fall. Because of the creation of voids, the broken roof occupies almost the same volume that it had originally plus that which the coal occupied, so that disturbance at the surface is small. The production of the coal planer is high.

A much simplified picture of coal-mine mechanization has been presented. Developments along that line, particularly rapid in the last decade, are still proceeding. Even today, although many mines are only partly mechanized, about five-sixths or more of all coal mined is mechanically loaded.

The first major task in underground mining—undercutting of the coal seam—was the first function to become mechanized, 25 percent having been cut by machines as early as 1900. The percentage in 1963 was 61. Similarly, hand drills have been replaced by power drills, the latter being used in 64 percent of total underground production by 1963. Continuous mining machines accounted for approximately 40 percent of total coal mechanically loaded underground in 1963. Mechanical loading has already been mentioned. Although some animals, mostly mules, still are used for hauling in small mines, they have been generally replaced by electric locomotives, rope haulage, belt conveyors, or shuttle cars.

Preparation

As a result of the developments in mechanization, the quantity of bituminous coal mechanically cleaned in the United States increased from 28 million tons (5 percent of total production) in 1927 to 289 million tons (63 percent of total production) in 1963.

In the early days of coal production, screening and hand picking of slate and rock at the working face constituted the preparation of coal. As time went on, crushing became an important factor in fitting coal to the needs of consumers. More recently, greater emphasis has been placed on quality of coal and removal of extraneous material. To meet this requirement and sales competition, coal washing or cleaning grew in importance; this operation has been carried out largely by machine. The introduction of mechanized mining, which does not differentiate between coal and impurities has given great impetus to coal preparation. Nearly two-thirds of all coal mined in the United States is now mechanically cleaned.

Cleaning consists of removing high ash bands, rock, ash-forming material, and sulfur-bearing components of coal. Sulfur occurs generally in two forms—inorganic matter such as pyrite (iron sulfide), and organic sulfur compounds that are inherent in the basic coal substance. The latter is not now separable, whereas part of the inorganic sulfur is separable.

Separation of impurities from coal is based primarily on differences in density, the sep-

arable impurities being heavier than an equal volume of coal. The natural force of gravity is employed in addition to forces such as centrifugal force and those introduced by agitation, jigging, flow of water, and the like. Differences in density are utilized by separation in air, water, chemical solutions, suspensions, or slurries, and air flotation with special wetting agents.

Coal-Cleaning Systems

The most popular system for cleaning coal in the United States is the use of jigs. In this unit, the raw coal feed is stratified in water into a series of layers of different density by mechanical impulses applied to the water. Other systems use the flow of water to achieve cleaning. In the cleaning of fine coal, the coal washing table utilizing a flow of water combined with a differential movement of the table itself is used widely in this country.

In the dense-medium processes, coal is separated from its associated impurities by suspension of finely divided solids in water, aqueous solutions of inorganic salts, and organic liquids. Magnetite, pulverized, refuse, loess, sand, and barites are frequently used as suspended solids in the process. Calcium chloride solutions are the predominant means of cleaning coal using soluble inorganic salts. In this process, the separating medium is adjusted to achieve a predetermined gravity of separation, permitting the clean coal to float and the heavier refuse materials to sink in the bath.

For the cleaning of very fine sizes of coal, flotation procedures must be employed. In these, the mixture of coal and impurities is fed into a water bath, flotation agents are added, and the bath is aerated with small bubbles of air. The flotation agent (such as kerosine plus pine oil) wets only the coal particles, which are attached to air bubbles, lifted to the surface of the water, and skimmed off mechanically.

Centrifugal force is employed, in addition to gravity, in the Humphrey spiral, in which the coal to be cleaned and water are passed down a spiral trough. This combination of forces has taken another form in the cyclone separator and thickener, in which the principle of the cyclone is employed as in dust, sawdust, and grain collectors with pneumatic systems.

In other systems, air flows counter to the pull of gravity and separates coal and impurities. Again, suitable takeoffs are provided. This process is known as elutriation when applied to dusts and other fine materials for classification or segregation purposes; when used with coal it is known as air cleaning. A combination of moving air and sand, often in a cone-shaped vessel, is widely used.

Processes have also been developed for drying, removal of dust, addition of calcium chloride to prevent freezing, and surface oiling for cleanliness.

Crushing

The crushing of large lumps into smaller ones permits easier handling and cleaning and meeting market requirements. Before about 1930 the largest sizes were at a premium, and mechanical cleaning was little used. The only reason for crushing, therefore, was to reduce large lumps so that they would pass through the tipple. In subsequent years, however, crushing became essential to meet the customer demand for smaller sizes for use in mechanical stokers, as well as for mechanical cleaning.

Treatment for Allaying Dust

Although dust on coal may be negligible in comparison with the total weight, it creates a nuisance or even a hazard from explosion. Much experimentation has been carried on to develop surface processes for allaying coal dust (as distinguished from dust problems in underground coal mines). Such treatment also tends to prevent freezing of wet coal, reduces windage to prevent freezing of wet coal, reduces windage loss of fines in transit, improves burning performance at times, reduces the tendency toward spontaneous heating during storage, and reduces air slacking and distintegration.

The materials used for such surface treatment are (1) water in conjunction with wetting agents (organic chemical compounds that cause water to spread into a thin film and wet the coal surface readily), (2) calcium chloride with or without various admixtures, and (3) oil or other petroleum products. The predominant treating agent has been oil, except during World War II, when its use was restricted.

Combustion

Most of the bituminous coal produced in the United States is burned in boilers or furnaces to obtain thermal energy for generating electricity, processing raw and manufactured materials, and providing comfort heating in industrial and commercial establishments, institutions, and homes. The electric utility industry is the largest consumer of bituminous coal, accounting for 51 percent of consumption in the United States in 1963. A significant amount of coal is consumed annually for calcining to make cement, lime, gypsum, alumina, and magnesia, and for firing ceramic products. The use of bituminous coal for residential heating and for rail-motive power has declined in

recent years in favor of petroleum and natural gas, but these markets may be partly recaptured within the next 10 years if research investigations now in progress result in feasible and economic processes for converting coal to methane, and in a coal-fired gas-turbine locomotive having a comparatively high degree of availability.

Broadly speaking, combustion is accomplished conventionally by burning coal on a grate, in suspension, or by combinations of these methods.

Basically, a grate is a device on which a bed of coal is ignited and burned in place. Grates may be horizontal or inclined, fixed or movable, vibrating or modulating, but each kind is designed to allow air for combustion to pass through the bed of coal, and to permit removal of ash and clinker. The coal may be charged to the grate batchwise by manual means, or more or less continuously by a mechanical stoker. Grates for residential-heating furnaces are comparatively simple devices, whether they are fired manually or with a mechanical stoker. Grate-stoker combinations for commercial and industrial use are designated as single-retort, multiple-retort, chain, traveling, and spreader stokers. The latter type combines the features of combustion on a grate and in suspension.

For suspension burning, two methods are employed. The coal is pulverized and blown into the combustion chamber with approximately 10 percent of the combustion air, the remainder of the air being supplied as secondary air to complete combustion in the furnace. The ash is removed dry or as molten slag, depending upon the design of the furnace. In the so-called dry-bottom furnace approximately 50 percent of the ash is carried out of the furnace with the products of combustion. Dust-collecting devices remove from 50 to 98 percent of this gas-borne ash. In wet-bottom furnaces less coal ash is carried out with the products of combustion than in dry-bottom furnaces. The other method involves blowing or mechanically throwing crushed coal into the furnaces, where most of it falls on a dump- or traveling grate. Part of the coal burns in suspension, and combustion is completed on the grate. This method generally is referred to as spreader firing and, as mentioned previously, incorporates the features of both grate and suspension firing. Almost all of the bituminous coal used by the electric utility industry is burned in pulverized-coal-fired furnaces, and much that is burned for industrial purposes is burned by spreader firing. The cyclone furnace, which is growing in importance in the utility and industrial fields, is a form of suspension burning. Crushed coal is blown into a cylindrical furnace, and tangentially admitted secondary air imparts vortex motion to the coal and gases. Part of the coal burns in suspension and the remainder, which is trapped in liquid coal-ash slag on the walls of the furnace, burns before the slag is discharged from the furnace. Cyclone furnaces remove about 90 percent of the coal ash as molten slag.

The choice of the type of firing depends upon a number of factors, chiefly the kind and quality of the coal and the amount of thermal energy desired within a given space for equipment. Generally, suspension burning provides more thermal energy than grate firing per unit volume of furnace. However, the capital investment for grate-stoker furnaces is less than that of pulverized-coal-fired furnaces below a certain capacity and vice versa. At the present time, the electric utility industry, which has boilers that generate over 4 million pounds of steam per hour, is based almost exclusively on the principle of suspension burning. To obtain greater thermal efficiencies, the utility industry is installing steam generators capable of steam temperatures up to 1,200° F and pressures of up to 5,000 pounds per square inch, with capacities up to 6.5 million pounds of steam per hour; these specifications were unheard of 15 years ago.

The trend to larger utility boilers has resulted in improving the steam-electric utilities national average heat rate from 15,700 Btu per kwhr in 1946 to 10,500 Btu per kwhr in 1963, while heat rates for a single plant during that period have shown improvement from the 10,608 Btu per kwhr in 1946 to 8,400 Btu per kwhr or slightly under in 1963. This represents a decrease in coal requirement in power generation to approximately 0.7 pound per kwhr or less at some plants. The national average is 0.86 pound per kwhr.

Carbonization

Coal carbonization, i.e., the destructive distillation of bituminous coal by heating it in the absence of air, is a process by which bituminous coal is converted into coke, gaseous, and liquid products. With the increasing use of coke as metallurgical fuel and of the liquid products for direct commercial uses or as starting materials for the manufacture of chemicals, carbonization has grown into one of the United States' most important industries. Approximately one-fifth of the coal consumed in the United States in 1963 was used for the production of coke and coal chemicals. The production of slot-type and beehive coke in 1963 totaled 54,278,000 tons.

Most of the coke produced is used in blast furnaces, and a comparatively smaller amount is used in foundry cupolas. The principle of smelting iron in the blast furnace has remained virtually unchanged since its first introduction in the early part of the 14th century. Successive

layers of iron ore, limestone, and coke are charged to a tall, refractory-lined steel shaft, and preheated air is admitted under pressure, through tuyeres located near the bottom of the shaft. The preheated air creates a combustion zone, induces partial burning of the fuel, and forms carbon monoxide by reaction with the carbon in the fuel. The carbon monoxide, in turn, reduces the iron oxide ore to metallic iron, but the temperature is not high enough to melt the associated impurities in the ore. These impurities, consisting primarily of aluminum silicates (gangue), are fluxed with the limestone to form a slag, which is fluid at about 2,500° F, well below the 3,000° F temperature in the combustion zone of the furnace. This fluid slag and the molten iron are drawn off periodically through separate taps at the base of the furnace, and the iron is cast (into pigs) or transported hot for further processing.

Charcoal was the original and chief source of fuel used in the blast furnace until the latter part of the 19th century. Coke, although first used in Europe in 1735, did not become an important blast-furnace fuel in the United States until long after the production of beehive coke began in 1841. Slot-type oven coke was first introduced in the United States in 1893, and its metallurgical use increased gradually until, in 1919, it exceeded that of beehive coke; it is now used almost exclusively.

The beehive coke oven is a firebrick chamber, approximately 12 feet in diameter and 7 feet high, with an arched roof, whose inside shape resembles an actual beehive. The ovens, built beside one another with a retaining wall between, extend in long rows, and are usually located near the coal mine. Coal is charged into the oven, which holds about 6 tons of coal, through a hole or trunnel head at the apex of the dome, and is leveled. Coking is started by the heat retained in the walls of the oven from the previous operation, or by heating the oven before charging. Almost immediately after charging, gas is evolved from the coal on the coal surface and in the space above. Air is introduced through a side door to support combustion. Coking proceeds downward, from the top of the coal charge to the floor of the oven. The products of combustion and any unburned gases escape through the charging hole at the top. When coking is complete, the door is opened and the coke is quenched with water and withdrawn from the oven. The beehive process requires the use of high-grade coking coals and a long coking time (2 to 3 full days). The coke produced is hard and dense, and large in size.

Various types of slot ovens have been designed and used to recover valuable chemical products and to obtain coke whose quality can be more carefully controlled. Another favorable factor concerning slot ovens is that coal blends may be used. In the slot-type coke ovens, the coal charge is carbonized without direct contact with the heating gases and the distillation products are recovered completely. Although beehive-oven construction involves a lower capital investment, the value of the chemical products recovered from the slot-type ovens is usually more than enough to offset the greater cost of oven construction, so that gradual replacement of the beehive by the slot-type oven has occurred. In the early development of these ovens, the heat required for carbonization was supplied either in horizontal or vertical flues. Recently, however, the vertical flue oven has found wider acceptance because it is more flexible in allowing the use of different fuel gases.

The slot-type coke oven is a long, narrow, silica-brick chamber, in which the coal is carbonized by heat supplied by the combustion of fuel gas in the flues that are built in the refractory-brick walls separating each of the ovens in the battery. Slot-type coke ovens vary in size and capacity. The small ovens, used in small gas plants, coke approximately 4 tons of coal per charge, while the larger ovens, used primarily for production of metallurgical coke, have a capacity of 20 tons or more. The larger ovens are usually 37 to 45 feet long, 9 to 15 feet high, and between 1 and 2 feet wide. An average sized oven with a width of approximately 1½ feet will hold about 17 tons of coal charged at 50 pounds per cubic foot bulk density. For a normal carbonizing time of 17 hours, the capacity of the oven is about 24 tons of coal per day.

Each oven has three or four charging holes. The coal, usually crushed so that 80 percent will pass through a ⅛-inch screen, is dropped through these holes into the oven and the resulting cone-shaped piles are leveled to permit uniform coking, better product recovery, and to facilitate coke removal through the side door. The manufacture of coke for blast furnace use requires 12 to 18 hours, depending on the oven width and the carbonization temperature, while foundry coke production generally requires 20 to 24 hours. After coking is complete, the oven doors are removed and the coke is discharged and quenched with water sprays.

To prevent deterioration of coke ovens that results from cooling and reheating, coke ovens are not allowed to remain empty for any considerable length of time. If the demand for coke decreases, the volume of fuel gas and the flue temperatures are reduced so that the coking period and, hence, coke oven operation is lengthened. As a result, the coke produced will vary somewhat, depending on the capacity at which the ovens operate. Although there are no absolute criteria for defining coke qualities that will

insure the most satisfactory performance of the blast furnace, uniformity in coke size, structure, and other physical and chemical characteristics are desirable.

The coke must be strong enough to resist excessive breakage during handling and charging into the furnace to support the heavy column of materials at the high temperatures in the passage down the shaft. Chemically, the coke should be low in moisture, volatile matter, sulfur, and ash contents. In turn, coals are selected so that, when carbonized, they will produce cokes having the desired characteristics. A good blast furnace coke, as generally defined in the Eastern States, contains no more than 4 percent moisture or 2 percent volatile matter, nor more than 1 percent sulfur, and about 10 percent ash. The chemical composition of a good coking coal or blend is as follows: 4 percent moisture, with a maximum of 7 percent; between 28 and 35 percent volatile matter; 1.5 percent or less sulfur; and 7.5 percent or less ash.

Approximately 98 percent of the coke produced in the United States, is made in slot ovens, about 2 percent in beehive ovens, and a very small amount by various unconventional processes, such as chain-grate stoker cokers, Disco carbonizers, and Lurgi retorts. The unconventional processes may be classified as low-, medium-, and high-temperature carbonization processes depending on final carbonization temperatures attained. Low-temperature carbonization processes are those in which the final carbonizing temperature does not exceed 700° C. In high-temperature carbonization, the final temperature of the coke usually is above 900° C, and the temperature in the heating flue is still higher. Processes which operate at temperatures between these two figures are designated as medium-temperature carbonization processes.

Considerable research and development work on various low-temperature carbonization processes has been conducted for many years, but few have been economically successful. The basic differences in the various low-temperature carbonization processes are in the methods by which the necessary heat for carbonization is transmitted to the coal. One of the low-temperature carbonization processes that has created considerable interest in the coal-processing industry in recent years has been the application of fluidized solid-fuels techniques. The char from fluidized coking can be used efficiently as a powerplant fuel, but it is also known that the tar is not comparable to high-temperature coal tar, and most of the products that can be made from it by conventional methods are not commercially usable in our chemical industry. This does not preclude the eventual economic utilization of low-temperature coal tar, as research and development in processing methods and new products will, no doubt, open up new markets for low-temperature tar. The Bureau of Mines is active in this field at several of its coal research laboratories.

Other unique unconventional carbonizing processes which are either in commercial- or pilot-plant-stage production are (1) the traveling-grate stoker coker, (2) continuous rotary hearth ovens, and (3) formed coke processes.

About 100,000 tons of chemical coke per year is being made with traveling-grate stoker cokers. This process does not require external heat; coal is carried on moving grates through a horizontal furnace, where required temperatures are generated in the bed by controlling the admission of small amounts of air. The hot coke feeds to a finishing shaft furnace and is quenched at the bottom of the furnace by a recycled gas mixture (nitrogen and carbon dioxide). Heat is recycled to preheat the air used in the first stage.

Pilot operations of a rotary hearth oven in southern Virginia indicate that this process is capable of achieving coking rates about 3.5 times that of conventional-type beehive-coke ovens. Although in principle this process is similar to the traveling-grate stoker coker, the furnace design actually is a long tunnel bent into the form of a circle enclosed in a big shell or cap. Another difference is that the whole bed or solid hearth rotates along with the coal. Coal is fed in at one point and coke comes out after completion of the circle 3 hours later. Operating temperatures of 2,400° F is comparable to standard slot-oven coke practice. A second pilot plant was completed in 1964 in Wyoming to test western coking coals.

Those processes which convert noncoking coal into a carbonaceous fuel suitable for various industrial and metallurgical applications by a combination of carbonization and briquetting steps are called formed coke processes. The most notable one tested thus far in a pilot plant stage in this country is the FMC Process. This is a multistage carbonizing process in which the coal goes through catalyzing, carbonizing, calcining, briquetting, curing, and final carbonizing stages. The final carbonizing temperatures range from 1,500 to 1,700° F, which indicate that it is a high-temperature carbonization process.

In addition to coke, four primary coal-chemical materials—tar, ammonia, light oil, and gas—are recovered at oven-coke plants. Initial cooling upon leaving the carbonizing chamber results in the condensation of the heavier high-boiling constituents comprising coal tar; further cooling with water and scrubbing with sulfuric or phosphoric acid effects the recovery of ammonia either as an aqueous solution or in the form of ammonium sulfate or diammonium

phosphate; still further cooling, followed by oil washing, removes light oils consisting of benzene, toluene, xylene, solvent naphtha, and naphthalene. After this point in the system, only gas remains as the final primary product. Coke-oven gas, which consists mainly as hydrogen and methane, is used mainly as fuel. Only 2 of the 62 active oven-coke plants processed their coke-oven gas for the recovery of hydrogen which in turn was used to manufacture synthetic anhydrous ammonia. This could be changed, however, as new facilities for processing coke-oven gas will be constructed at the largest coke plant in the United States. This company also proposes to build a 400,000-tons-a-year anhydrous ammonia plant to utilize the hydrogen recovered from the coke-oven gas.

Virtually all of the light oil recovered at oven-coke plants is processed by the producing companies. In order to produce light-oil derivatives with purity comparable to similar materials produced from petroleum feedstocks, coke-oven operators are modernizing and constructing new modern refining facilities. Two of the larger coke plants already have installed such facilities, and more can be expected to be constructed in the future.

Gasification

Gasification processes involving the use of coal or coke are used to manufacture gases having specific characteristics, depending on the end uses contemplated. Since reserves of natural gas are limited and may have to be supplemented by gases produced from coal, a great deal of attention has been directed, both in the United States and abroad, to the development of economic processes for such gas production.

Coal can be gasified with steam and air or oxygen, at atmospheric or elevated pressure, to produce synthesis gas (for chemical manufacture, production of hydrogen and synthetic liquid fuel, etc.) and producer gas (for industrial heating). In a two-step process, synthesis gas produced from coal gasification can be catalytically transformed to high-Btu pipeline gas. Coal can also be gasified in place, underground, with air or oxygen, to produce a gas suitable for power generation and other industrial uses.

The underground gasification of coal, explored on an experimental basis in the United States and abroad, is uneconomic under present conditions. This process is, however, being used in the U.S.S.R. for production of gas for power generation.

Synthesis gas, a mixture of carbon monoxide and hydrogen, can be produced by passing air (or oxygen) and steam alternately or continuously through a bed of hot coal or coke. Synthesis gas is now being produced on a commercial scale abroad by passing oxygen and steam continuously through a bed of coal, under pressure, and, in the Sasol plant in South Africa, is being used for the production of liquid fuel. It is also produced by entraining pulverized coal in a stream of oxygen and steam.

Producer gas is made by passing a mixture of air and steam continuously through a hot fuel bed, with the resultant gas being used for industrial process heating.

The catalytic methanation of synthesis gas produces a high-Btu gas, is technically feasible and, when economically practicable, could be used to produce a substitute for natural gas. Research is in progress to improve this process, to permit one-step conversion, at reduced cost.

In addition to the conventional techniques described earlier, the Federal Bureau of Mines in cooperation with the Atomic Energy Commission, is investigating the possibility of using nuclear fission to supply the reaction heat required for the direct gasification of coal with steam to produce increased yields of synthesis gas. Research is now in progress, with current tests involving the use of a simulated nuclear reactor, i.e., an electrically heated reactor.

The coal required and the yields and quality of gas produced in each of the above processes vary greatly, depending on the operating conditions and, in turn, on the end applications contemplated.

Hydrogenation

Hydrogenation of coal at elevated pressures and temperatures is another process for converting this valuable and plentiful solid fuel to other products that have potential value and a large established market, e.g., to synthetic liquid fuels (motor and aviation gasoline, and liquefied petroleum gases), and chemical intermediates or raw materials, and supplements to or substitutes for natural gas.

The liquid-phase hydrogenation of coal was used in Germany during World War II to produce gasoline and oil products. The direct hydrogenation of coal is being investigated in the United States on a laboratory and pilot plant scale and was evaluated in the demonstration plant at Louisiana, Mo. The data obtained from these studies have indicated that, although the process is technically practicable, the costs involved do not permit commercial exploitation of the process under present economic conditions.

Attention has also been directed toward the possibility of hydrogenating coal to produce marketable chemicals or chemical raw materials, such as benzene, toluene, phenols, etc. The type and quantity of products are determined by

the operating conditions. Similar products are obtained from other sources, as byproducts of coal carbonization and petroleum refining, and are currently more economically produced. Hydrogenation of coal to produce gaseous hydrocarbons (equivalent to natural gas) is also under investigation.

USES

Most of the coal produced is burned for heat and power production, or carbonized to produce metallurgical coke. Although there are other uses of coal and potentially important new uses are now being developed, these are of relatively minor importance in terms of large tonnages in the actual and present utilization scheme.

For example, the gasification of coal, which has had an important role in American industry, has undergone many changes. Producer gas, formed by passing limited and controlled quantities of air and steam through ignited coal, found extensive use in industry for operations requiring heat, such as coking and ceramic firing.

Coal, when coked, produces a valuable gas (about 10 to 11,000 cubic feet per ton of coal) of good heating quality (about 550 Btu per cubic foot) with a composition that makes its utilization as raw material for synthetic chemical production feasible. Such utilization is now beginning in the United States. This gas has been used over the years as a domestic gas and for industrial purposes.

Coke has been the source of much water gas, a mixture of mainly hydrogen and carbon monoxide. This gas is produced by the action of steam on incandescent coke and has a heating value of about 300 Btu per cubic foot. For many years, enriched in heating value to 500 to 550 Btu by gases from cracked oil, carbureted water gas has served as domestic gas. As the ratio of hydrogen to carbon monoxide is adjustable by chemical reaction, water gas can provide hydrogen for ammonia synthesis, for hydrogenation of oils to make margarine and cooking fat, and to convert coal to chemicals and liquid fuels. Water gas also serves as raw material for the synthesis of motor fuels, methanol, higher alcohols, and other chemicals.

The advent of natural gas (mainly methane) and its distribution in volume in recent years have caused changes in the production and use of gas from coal in almost all fields, whether its use be as a fuel or as a chemical raw material. Methods are now being studied (and used to some extent abroad) for converting coal to methane.

Most coal produced today is burned to provide energy—to generate electricity, provide process heat, and heat for domestic use. Coal is burned for space heating, whether heat distribution is by warm air, hot water, steam, or electricity. It is burned to supply hot water and steam for many purposes. One of the most important of these numerous uses is the generation of electric power for lighting, manufacture, transportation, communication systems, air conditioning, domestic appliances, and the like. The combustion of coal and its control and application for technical purposes are being intensively studied and developed. In fact, burning of coal has, to a large degree, become a science. Pulverized coal can now be moved and handled like a fluid (analogous to oil and gas). Combustion has developed from simple burning on rudimentary grates, stoves, and furnaces to a highly complex operation, instrumented for efficiency and automatically controlled.

The largest and fastest growing market for coal is the electric utility industry. The technologic advances in coal mining, preparation, and combustion equipment design have combined to increase efficiency of power generation to a point where competitive fuels would require large reductions in price to compete commercially with coal. Although plant efficiencies vary considerably, the 1963 national average for electric utility plant consumption of coal was 0.86 pound of coal per kwhr, with new plants built for operation on approximately 0.7 pound of coal per kwhr. In 1920, 3 pounds of coal was consumed in the United States for 1 kwhr of electricity.

As noted earlier, coal is also burned or used to supply heat for industrial process use, in the manufacture of cement, and other products, with the ratio and quantity of coal used determined by advances in process and equipment design. The ash may be used in the manufacture of rock wool for insulation and in applications described in the "Byproducts and Coproduct" section.

The use of coal for motive power and residential heat has decreased with the advent of petroleum products and natural gas and the more convenient equipment and handling the use of these products entails. Attempts are, however, being made to develop techniques that would permit the coal industry to maintain and to expand its present share of these markets. Although the increasing use of competitive fuels appears inevitable, advances in the technology of coal gasification, the conversion of coal to gaseous and liquid fuels, may afford a new and better opportunity for coal to recover its share of these markets.

The second largest outlet for coal is the steel industry. Approximately one-fifth of the coal consumed in the United States is used for the production of coke for metallurgical use and, as byproducts of the carbonization process, of

coal chemicals. Almost 1½ tons of coal is needed to produce 1 ton of coke which, in turn, is required to make about 1¼ to 1½ tons of pig iron. Bituminous coals having acceptable properties and characteristics are carbonized at high temperatures to produce coal tar and light oils which serve (1) as raw materials for organic chemicals like synthetic rubber, detergents, plastics, photographic materials, flavor and perfume chemicals, explosives, and medicinals, and (2) after comparatively slight processing, as wood preservatives, disinfectants, animal dips, and road and building materials.

Low-temperature carbonization (at 900° to 1,000° F compared with about 2,000° F for high-temperature or coke-oven carbonization) is a little-practiced but promising use of lower rank coals for producing smokeless fuel, industrial carbons, and substantial quantities of low-temperature tar and oils. A prototype unit for the low-temperature carbonization of lignite has been constructed and operated in Texas for the production of a char suitable for use as a boiler fuel. The carbonization of lignite does not result in the production of coke; a char is produced which, on further processing and recarbonization, could be used in some metallurgical applications. The commercial exploitation of this process, however, depends on the realization of a market for the liquid and gaseous products. When economical operation of low-temperature carbonization is achieved, it should result in expansion of coal consumption and the use of large and virtually untapped fuel reserves.

BYPRODUCTS AND COPRODUCT RELATIONSHIPS

The production of coal chemicals as byproducts of coke production is established and will not be considered in this section. However, the use of residual products from combustion of coal, i.e., fly ash, flue dust, coal ash and cinders, as well as rejects from the preparation plant, is a possible means for either recovering or producing various chemicals and materials. These products are and may continue to be used increasingly by the building industry in the manufacture of cement and concrete products and for such uses as the construction of roads.

Fly ash is used primarily in the building industry, in the manufacture of concrete, building stones, and cinder blocks, and in asphalt highway construction. Coal cinders have also found application in the manufacture of cinder blocks for the building industry.

Coal furnace flue dust, a commercial source of germanium in England, is not processed commercially in the United States. Germanium and other elements (such as vanadium, lithium, and uranium) also can be recovered from coal ash. Coal ash was used during wartime as a source of alumina, producing 1 ton of alumina from 10 to 12 tons of coal, and this process is now again attracting commercial attention. Lignitic uranium ores of commercial importance have been discovered in North Dakota.

Washery refuse has, in the past, been used as a source of sulfur. Two companies in the United States are now using preparation plant rejects for the production of lightweight aggregates on a commercial scale.

ALTERNATE MATERIALS

Natural gas and petroleum, considered in other chapters, and atomic energy are competitive with coal as sources of energy. Much theoretical and applied research has been pursued that would advance the possibility of developing new and unconventional sources of energy to substitute for the mineral fuels used today. Atomic energy is now a reality and will grow in importance. However, when the exploitation of one or more new sources of energy is contemplated, consideration must be given to the availability of fuels, the character and magnitude of the demand for power, and the anticipated cost of power produced from the new sources. Under these conditions, most estimates indicate that complementary energy sources will not significantly affect the energy market before the 1980–2000 period.

RESERVES

The United States is richly endowed with mineral-fuel resources. It has one-third of the geologically estimated coal and lignite reserve of the world, one-tenth of the proved petroleum reserve, and about one-third of the world's proved natural-gas reserve. The United States also is the greatest producer of solid, liquid, and gaseous mineral fuels as a whole. In 1963 the Nation produced 22 percent of the world production of coal, less than 1 percent of world lignite, 30 percent of all petroleum and 60 percent of the natural gas.

The Federal Geological Survey estimated the remaining coal reserve of the United States, including Alaska, at 1,660 billion tons as of January 1, 1960. The reserve estimates include beds down to 14 inches thick for anthracite and bituminous coal and down to 30 inches or more thick for subbituminous coal and lignite. The reserve is largely geologically inferred, and estimates did not allow for mining losses or recognize that beds less than 2 feet thick are not

economically minable by present underground methods. Investigations by the Bureau of Mines and others have shown that, on the average, about 50 percent of the coal is recovered in underground mining. Losses include coal left in pillars, in areas around oil and gas wells, under towns, railroads, roads, and streams, in river beds, in thin and impure beds, and in isolated areas not readily accessible for mining.

Table 3 lists the recoverable reserves of coal in the United States, as of January 1, 1960. The recoverable total of 830 billion tons represents one-half the total resource and includes 380 billion tons of bituminous, 224 billion tons of lignitic, 218 billion tons of subbituminous, and 8 billion tons of anthracitic coal; however, the average heating values of the several ranks of coal decrease from 14,000 Btu for low-volatile bituminous coal to 6,700 Btu for lignite. Therefore, these coals have also been compared, in terms of energy obtainable from them, by converting the tonnages given in column 1 to equivalent tons of bituminous coal of 13,000 Btu per pound. Thus, a reserve of 224 billion tons of lignite equals 115 billion tons of 13,000-Btu bituminous coal in heating value.

Tables 4 and 5 show the distribution, by rank and geographical location, of these coal reserves on the basis of equivalent heating value. According to this method of evaluation, about 54 percent of the minable reserve of coal and lignite is in the Eastern and Interior provinces and 46 percent in the Northern Great Plains, Rocky Mountain, Gulf, and Pacific provinces.

The Eastern Province consists of Pennsylvania, Ohio, Maryland, West Virginia, Virginia, eastern Kentucky, Tennessee, and Alabama; the Interior Province consisting of Illinois, Indiana, western Kentucky, Iowa, Missouri, Kansas, Oklahoma, and Arkansas; and the northern Great Plains, Gulf, Rocky Mountain, and Pacific Provinces consisting of North Dakota, South Dakota, Montana, Idaho, Wyoming, Colorado, Utah, Arizona, New Mexico, Texas, Washington, Oregon, and California.

TABLE 3.—*Potential recoverable reserves of various ranks of coal as of January 1, 1960*

Rank of coal	Billion short tons (1)	Bituminous coal of 13,000 Btu per pound calorific value, equivalent billion short tons (2)	Total coal reserves on Btu basis, percent (3)	Heating values used in conversion, Btu (4)
Anthracite	8	8	1	12,700
Bituminous	380	395	58	13,500
Subbituminous	218	159	24	9,500
Lignitic	224	115	17	6,700
Total	830	677	100	

TABLE 4.—*Distribution of recoverable coal reserves in terms of Btu value, by ranks and provinces*

[Weight basis]

Rank of coal	Equivalent 13,000 Btu coal, billion short tons				
	Anthracite	Bituminous	Subbituminous	Lignitic	Total
Eastern	6.0	218			224.0
Interior	.1	205			205.1
Northern Great Plains, Rocky Mountain, Gulf, and Pacific	.4	116	136	119	371.4
Total	6.5	539	136	119	800.5

TABLE 5.—*Distribution of recoverable coal reserves in terms of Btu value, by ranks and provinces*

[Percentage basis]

Rank of coal	Anthracite	Bituminous	Subbituminous	Lignitic	Total
Eastern	1	27			28
Interior		26			26
Northern Great Plains, Rocky Mountain, Gulf, and Pacific		14	17	15	46
Total	1	67	17	15	100

Eastern and western coals differ sharply in rank. Virtually all of the Eastern and Interior province coals, except anthracite, are caking bituminous coals. Coals of the Appalachian region are medium to strongly coking, and, in 1963, supplied 93 percent of the coal used for making coke. On the other hand, 70 percent of the coals of the Northern Great Plains, Rocky Mountain, Gulf, and Pacific provinces are subbituminous and lignitic. These coals do not cake on heating.

As a basis for comparison of fuel reserves, committees of the American Petroleum Institute and of the American Gas Association estimated as of December 31, 1963, that the proved United States recoverable reserve of crude oil was 30.97 billion 42-gallon barrels and that of natural-gas liquids was 7.67 billion barrels, making a total of 38.64 billion barrels of liquid hydrocarbons. The American Gas Association committee estimated the proved reserve of natural gas at 276.2 trillion cubic feet; a recent estimate by the Federal Geological Survey of oil equivalent in oil shale deposits in Colorado, Utah, and Wyoming includes 600 billion barrels of oil in shale yielding 25 gallons or more oil per ton.

To satisfy the large and still increasing demand for liquid fuel, more petroleum deposits must be discovered, more petroleum imported, or, from the standpoint of self-sufficiency, syn-

thetic liquid fuels made from natural gas, coal, or oil shale. Each of the procedures probably will be employed to some extent, depending on economic and national defense conditions. Additional domestic reserves of petroleum are being found at a rate almost adequate to supply the increasing domestic demand. Development of oil deposits in South America, Canada, and the Middle East is making oil available for importation to the United States under peacetime conditions and for supplying the growing demand for other countries. Bureau of Mines research at Rifle, Colo., has demonstrated that liquid fuels can be made from oil shale at comparatively small increases over prices prevailing in recent years for corresponding fuels from petroleum. Large reserves of coal and lignite also can be converted to liquid fuels.

Reserves for different mineral fuels are not calculated on the same basis. Proved reserves for liquid and gaseous fuels are increased each year by new discoveries and extensions of fields and decreased by the year's production. More oil and gas reserves will be proved in the United States; in this respect, these fuels differ from coal and oil shale. Solid-fuel reserve estimates are based largely on geological observations after limited exploratory drilling especially those for Western States. Future exploration is not likely to add much to the solid-fuel reserve, and revisions may be downward as more data are obtained in the various coalfields.

Therefore, to compare fuels reserves the quantities should be expressed in a common energy unit, such as British thermal units, and indicate whether they refer to proved, measured, or indicated material recoverable by current methods. Proved reserves of oil and gas meet the last qualifications. On the other hand, estimates of recoverable coal include considerable quantities of inferred and not proved material, as well as beds from 14 to 28 inches thick or 2,000 to 3,000 feet below the surface and thus not economic to mine at present. The Federal Geological Survey, on the basis of existing data and its reestimation of reserves in 10 States, concluded that one-fourth of the recoverable reserve (see table 6) would fairly represent the proved (measured and indicated) reserve of coal commercially recoverable by current production methods. Estimates of the total inferred recoverable reserves of petroleum and natural gas are compared in table 6 with the minable reserves of coal (including measured, indicated, and inferred) without reference to the cost of mining as a measure of relative reserves of the respective fuels. Column 1 of this table gives the proved (measured and indicated) reserve of coal now commercially minable, proved reserves of petroleum and natural gas, and of oil potentially recoverable from oil shale deposits averaging not less than 30 gallons of oil a ton.

TABLE 6.—*Estimated recoverable mineral-fuel reserves of the United States, as of January 1960*

Kind of fuel	Reserves, quadrillion Btu		Percent of total fuel reserves	
	Proved	Total potential	Proved	Total potential
Coal	5,400	22,000	87.1	77.2
Petroleum, including natural-gas liquids	215	2,355	3.5	8.3
Natural gas	285	1,100	4.6	3.9
Bitumen from bituminous sandstone	10	60	.1	.1
Oil from oil shale	290	3,000	4.7	10.5
Total	6,200	28,515	100.0	100.0

Column 2 gives the recoverable (equivalent to one-half of the grand total), measured, indicated, and inferred coal reserve without any deduction for thin or deep beds, the unproved reserves of oil and gas estimated on the basis of favorable geological formations, and the estimated potentially recoverable reserves of oil from indicated, measured, and inferred oil-shale deposits averaging not less than 25 gallons of oil a ton.

The estimated total coal reserve (including inferred and difficultly accessible coal) is eight times the reserve of coal recoverable under current conditions. The estimated reserve of total oil and oil from oil shale is about 10 times the estimated proved reserve, and the estimated potential gas reserve is about four times the proved reserve. Obviously, coal is the dominant fuel in both estimates. It represents almost 90 percent of the total energy in the proved reserves and almost 80 percent in the potential reserve estimate. If coal had been used to satisfy the demand for liquid and gaseous fuels in 1963, many times as much coal would have been used as the 477 million tons of bituminous coal, anthracite, and lignite produced that year. This example illustrates the tremendous demands that will be made on the resources of coal, oil shale, fissionable minerals, and other sources of energy as gas and petroleum deposits become depleted. The life of these fuel reserves cannot be estimated because of the many variable factors involved. No one can accurately predict demands, new discoveries, and the effect of further technological developments. Estimates have ranged from 75 to 3,000 years supply for fossil-fuel reserves.

Most bituminous coals in the Western States are free burning and noncaking. Some of them are slightly caking but do not become plastic enough to form coke strong enough for blast furnace use.

Relatively small reserves of good coking coal occur in the Trinidad-Raton field of southern Colorado and northern New Mexico. This coal has been used for some years for making metallurgical coke. Bureau of Mines engineers estimate the reserve of coking coal in beds 3 feet and more thick as 850 million tons for the Trinidad field and 600 million tons for the Raton field. These estimates are made on the basis of Federal Geological Survey and other data.

Another coking-coal reserve of probably greater extent but poorer coking properties occurs in the Book Cliffs field of eastern Utah and western Colorado. The Sunnyside beds in Utah are supplying the coke ovens at Provo and Geneva, Utah, and Fontana, Calif. This coal has a high oxygen content and approaches the limit of suitability for making metallurgical coke with adequate physical properties for blast furnace use.

Some strongly coking, low-sulfur coals occur in Pierce and Kittitas Counties, Wash., but, unfortunately, they are high in ash and difficult to mine owing to pitching and faulting of the beds.

SOURCES OF STATISTICAL INFORMATION

The principal sources of statistical information on the bituminous-coal industry are Bureau of Mines publications, most of which are based upon detailed reports of production, mine operation, and distribution furnished by the producers. Additional information is obtained from sales agents, distributors, railroads, retail dealers, traffic associations, equipment manufacturers, consumers, and from other Government agencies such as the U.S. Department of Labor, the U.S. Department of Commerce, the Federal Power Commission, the Interstate Commerce Commission, and State mining departments. All of the economic phases of the coal industry are covered with the possible exception of cost of production. Information on detailed costs of production has been collected only when required by act of Congress for administrative purposes; there has been no requirement in recent years.

PRODUCTION, CONSUMPTION AND TRADE

Production

Through the turn of the century, the bituminous coal industry grew rapidly, almost doubling its production and capacity every 10 years (see table 7). From 1890 to 1910, production increased from 111 million to 417 million tons; it reached a wartime peak of 579 million tons in 1918. The number of mines and employees increased from 2,500 mines and 240,000 employees in 1875 to 9,300 mines and 705,000 employees in 1923. The value of production, at the mines, increased from $116 million in 1895 to over $2 billion in 1920.

From 1920 to the early 1930's, however, the general trend of production was downward—to a low of approximately 310 million tons in 1932. The number of mines and employees dropped to 5,400 and 406,000, respectively, and value at the mines declined to $407 million. The steady, normal growth of the industry came to a halt and gave way to excess capacity, which resulted in a severe depression for coal.

Not until 1940 did the industry as a whole emerge from the depression, following the passage of the Bituminous Coal Act of 1937 and the beginning of heavy war requirements. Production increased to a wartime peak of 620 million tons. To meet the heavy demands for energy during the postwar rehabilitation period, including the highest demands in history for exportation of U.S. coal, production climbed to its alltime peak of more than 630 million tons in 1947. Value f.o.b. mines in 1948 reached almost $3 billion, and the number of mines in 1950 exceeded 9,400. From these pinnacles, however, the drop has been severe, even disastrous for many mining companies and miners. Output in 1961 fell to 403 million tons, second lowest since the prewar depression year of 1939, having dropped previously to 392 million tons in 1954. Since 1961 the bituminous coal mining industry has staged a sizable recovery, reaching outputs of 422 and 458 million tons in 1962 and 1963, respectively. In 1963 the number of mines was 7,940, and value f.o.b. mines amounted to over $2 billion. Employment declined to 141,000.

Although an excess of coal-producing capacity is a bulwark of safety in emergencies, at other times it is a depressing factor in operations of the industry. On the basis of a 280-day work-year, capacity in 1923 was 885 million tons (565 million produced); in 1932, 594 million (310 million); in 1944, 624 million (620 million); and in 1963, 627 million (459 million). In 1944 most of the factors essential for capacity production were present, including a maximum supply of railroad cars and 6 to 7 days of operation per week. Because of the intangibles and complexities involved, attainable production is something less than calculated capacity.

TABLE 7.—*Growth of the bituminous-coal- and lignite-mining industry in the United States*

Year	Production (short tons)	Average value per ton	Number of mines	Men employed	Short tons per man-day	Percentage of underground production mechanically loaded	Percentage of total production	
							Mechanically cleaned	Mined by stripping
1918	579,385,820	$2.58	8,319	615,305	3.78	----------	3.8	1.4

A coal mine is not like a factory, that can be closed and reopened in part or in full to meet fluctuating demands. Because of natural conditions of water and gas accumulations, roof falls, and similar problems, particularly in underground mines, maintenance of idle or only partly used mines is costly. Coal must therefore be sold at almost any price to keep the plants going, to benefit from the advantages of steady output, and to hold out as long as possible for a change to the better. Only when prices are not commensurate with costs and when capital investment has been drained, do many mines close.

Increased efficiency in production and the ability of the industry to absorb some of the increased costs of mining have resulted from greater mechanization. As a further result, new and modernized mines generally are larger than older, nonmechanized mines, and many less efficient mines have ceased operation. In 1924, when less than 1 percent of underground production was loaded mechanically, only 18 percent came from mines having an annual output of 500,000 tons and over. By 1963 the mines in this size category, which represented only 2.8 percent of the total number of mines, produced 53 percent of the total production. In contrast, by 1963, mines producing less than 10,000 tons per year constituted 56 percent of the total number of mines and accounted for only 4 percent of total production. The intermediate mines, representing 37.2 percent of the total number of mines, accounted for 42 percent of total production in 1963.

Because of geographic and other factors, the industry did not lend itself well in the past to combined ownership among comparatively few large concerns, as is common in many other major industries. There are some large coal companies, however, and in recent years there have been some significant consolidations among companies. Nevertheless, there are still over 7,900 mines.

Besides commercial mines which sell their product in the competitive market, the industry includes many so-called captive mines, owned and operated by parent companies primarily to supply their own coal requirements. These mines furnished 14 percent of total U.S. production in 1963. The principal owners of captive mines are steel companies, electric power utilities, railroads, coke plants, and clay-product companies.

The rapid increase in mechanization in a comparatively short period, loss of markets to competing fuels, and increased efficiency in burning coal caused reductions in the number of men employed by the coal industry. Although em-

ployment dropped from a peak of 705,000 employees in 1923 to 142,000 in 1963, productivity increased from 4.47 to 15.83 tons per man per day. The latter figure is an average of 12.78 tons for underground, 38.87 for auger, and 28.69 for strip mining. Correspondingly, mechanical loading of coal underground increased from less than 1 percent in 1923 to 85.8 percent in 1963 and coal stripping from 2 to over 31 percent.

Consumption

Increased availability and consumption of petroleum and natural gas have brought drastic changes in coal utilization. Bituminous-coal and lignite consumption dropped from a peak of 594 million tons in 1943 to 367 million tons in 1958, but since has been on an upward trend (see table 8).

From 1944 to 1963 the coal industry lost 315 million tons of annual consumption in the following markets: 132 million tons formerly used by railroads; 98 million formerly sold by retail dealers; 49 million formerly used for general industrial purposes, excluding electric power utilities; 8 million formerly used by steel and rolling mills; and 28 million tons at coke plants. Over the same period, however, two groups increased their annual consumption of bituminous coal: Electric power utilities used 132 million tons more, and cement mills took 4 million tons more.

Over 40 percent of the total drop resulted from conversion of locomotives to diesel power. Experimentation with a gas turbine using coal as fuel is now in process in an attempt to recover at least some of the lost railroad market.

The decline of coal in the total energy market is indicated further by the fact that as late as 1945 coal (bituminous, lignite, and anthracite combined) contributed over 50 percent of our total energy supply, whereas by 1963 it contributed only 22.3 percent of the annual new supply (see figs. 1 and 2). From 1945 to 1963 petroleum and natural gas increased their contribution from 46 to 74 percent of the total supply. Waterpower remained constant at approximately 4 percent.

TABLE 8.—*Consumption of bituminous coal and lignite, by consumer class, with retail deliveries in the United States*

[1] Federal Power Commission.

[2] Bureau of the Census, U.S. Department of Commerce. Ore and Coal Exchange.

[3] Association of American Railroads. Represents consumption of bituminous coal and lignite for all uses, including locomotive, powerhouse, shop, and station fuel.

[4] Estimates based upon reports collected from a selected list of representative steel and rolling mills.

[5] Estimates based upon reports collected from a selected list of representative manufacturing plants.

[6] Estimates based upon reports collected from a selected list of representative retailers. Includes some coal shipped by truck from mine to final destination.

[7] The total of classes shown approximates total consumption. The calculation of consumption from production, imports, exports, and changes in stocks is not as accurate as the "Total of classes shown" because certain significant items of stocks are not included in year-end stocks. These items are: Stocks on Lake and Tidewater docks, stock at other intermediate storage piles between mine and consumer, and coal in transit.

[8] Canvass discontinued.

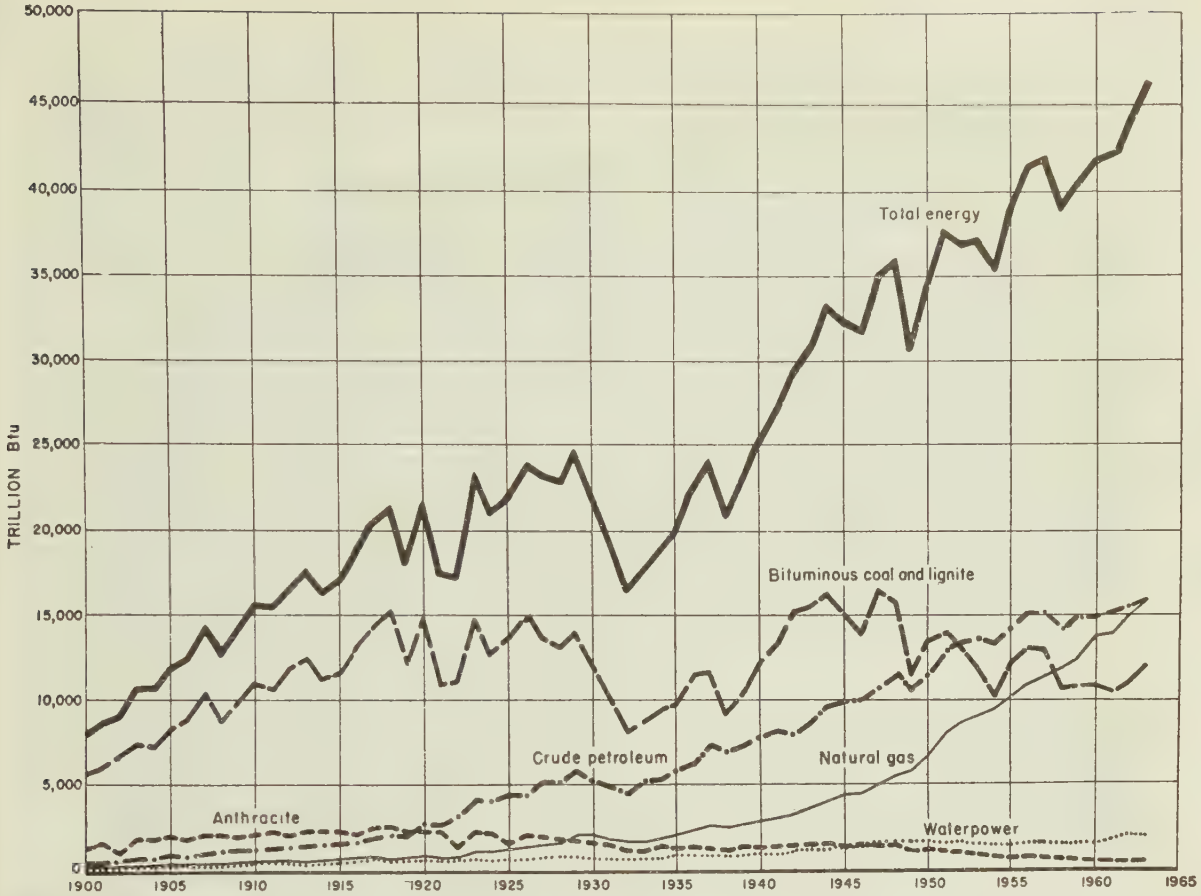

FIGURE 1.—Production of Mineral Energy Fuels and Energy From Waterpower in Continental United States.

Trade

The United States is both an importer and exporter of bituminous coal. Most of the imported coal comes from Canada and goes to a few States—from British Columbia to Washington, Montana, and Idaho, and from Nova Scotia to Maine and New Hampshire. The volume of imported coal is not great, however, compared with exports; it amounted to only 172,000 tons in 1963.

For many years Canada has been the principal customer for U.S. bituminous coal, averaging around 12 million tons a year during the past 5 years. Overseas exports, chiefly to Europe and Japan, have fluctuated widely, influenced primarily by changing rates of economic growth following postwar rehabilitation, high costs of indigenous production abroad, lack of adequate coking coals for the steel industry, vessel rates, and emergencies such as the Suez Canal crisis and severe winters. The availability of high-quality U.S. coal for export at economical prices is a result of the high productivity and efficiency of U.S. coal mining.

Total bituminous exports fluctuated between a peak of 76 million tons in 1957 and 35 million tons in 1961 during the past 7 years. They approximated 48 million tons in 1964.

In 1963 the six member countries of the European Coal and Steel Community (Belgium, France, Italy, Luxembourg, Netherlands, and West Germany) imported 21.4 million tons of coal from the United States (41.7 million tons in 1957), representing 85 percent of the total U.S. exports to Europe and 45 percent of world shipments. West Germany and Italy received 5.5 and 7.6 million tons, respectively, as compared to 15.5 and 8.8 million tons in 1957.

U.S. coal exports to Japan in 1963 (6 million tons), principally for the production of coke for blast furnaces, were double those of 1954 (3 million tons).

Notwithstanding increasing energy demands, coal production in most western European countries has been declining in recent years. This is due largely to the increased use of oil for industrial purposes, and to the discovery of natural gas in northeastern Europe. Nevertheless, because of the increasing energy demands and requirements for good quality coking coals in Japan, there are appreciable potentials for the increased exportation of U.S. coal.

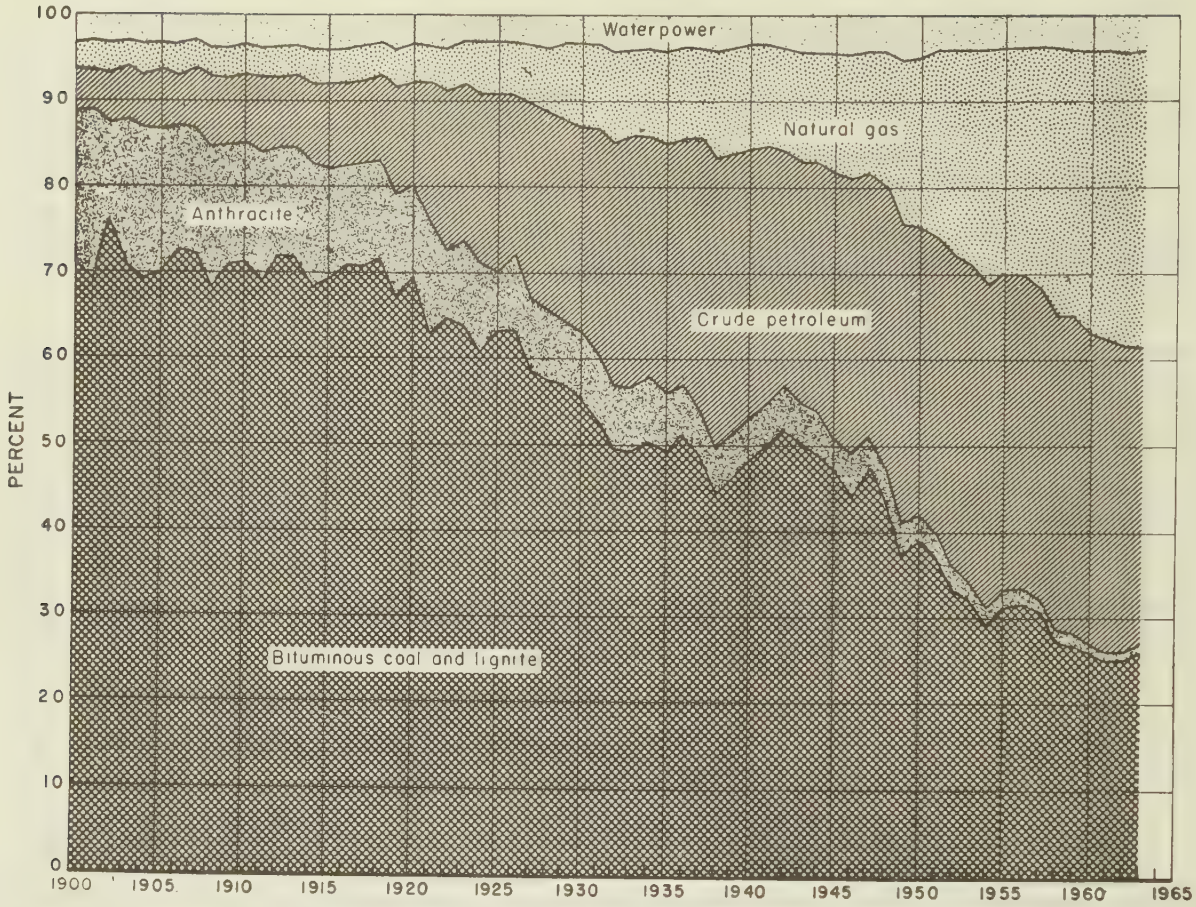

FIGURE 2.—Percent of Total Production of British Thermal Units Equivalent of Mineral Fuels and Energy From Waterpower in Continental United States

STRATEGIC CONSIDERATIONS

Coal is of vital importance in national emergencies, both as a source of energy and as a raw material for military and civilian requirements. The availability of adequate quantities of proper sizes and kinds of coal and their correct distribution aid in the timing and success of military programs. For the production of iron, steel, and electric power in the huge quantities required for national defense, coal is indispensable. Similarly, it is essential for manufacturing expansion generally, for space heating, and for the production of chemical raw materials such as toluene (a prime ingredient of explosives), benzene (vital in the manufacture of aviation gasoline and synthetic rubber), tar derivatives (used in the manufacture of a variety of important chemical products such as dyes, drugs, creosote oil), and fertilizers.

In manufacturing, 6 pounds of coal are used to make 1 pound of smokeless powder, 2 tons for a 1-ton bomb, and 220 tons for a modern tank. In addition to expanded requirements for coal for the kinds of uses to which it is normally put, coal must replace fuel oil when petroleum is diverted to more strategic uses and when oil supplies are limited because of transportation difficulties, including curtailment of offshore shipments because of submarines.

Coal is a bulk commodity consumed by the hundreds of millions of tons; in turn, it requires other materials and services that are scarce in national emergencies. Thus, the best preparation for defense (with regard to any basic commodity) is reasonably healthy operation during peacetime. To produce and distribute coal in wartime, adequate manpower must be available at mines, as well as transportation facilities, particularly open-top railroad cars. Stockpiling and distribution must be modified to allow for diversions to war industries, defense-production centers, and military bases. These other problems require planning and coordination of industry and Government, including the forecasting of requirements for coal, productive capacity, manpower equipment, supplies, and services so that the huge quantities required for

defense will be available when and where needed.

COST AND PRICE OF COAL

Two controlling forces operate to keep coal prices at levels that are not always commensurate with costs of production or with the attainment of reasonable profits—intraindustry competition and competition with oil, natural gas, and nuclear energy. Whereas even though under pressure of competition from only one of these two forces, coal prices might rise somewhat in keeping with increases in costs or with required profit margins, pressure from both makes price rises difficult under all but exceptional market conditions.

Current quotations on soft-coal prices at the consumer level are approximate but do throw some light on the market situation. Except for the annual average cost of bituminous coal at merchant coke ovens, the Bureau of Mines does not collect data on market prices of coal. The principal Government activities in this respect are (1) average wholesale and retail prices of soft coal, based on sampled coverage, as published by the Bureau of Labor Statistics; (2) monthly publication by the Interstate Commerce Commission of the average cost of railroad fuel purchased, at the mines; and (3) Federal Power Commission information pertaining to the cost of coal at electric power utilities. The coal-trade journals published some posted current wholesale prices, f.o.b. mine, usually in terms of high and low quotations.

The most valuable index of the trend of prices at the mines is the annual figures of average value per ton published by the Bureau of Mines. These data are on a national, State and county basis and are classified according to the method of mining. The national average value f.o.b. mines has fluctuated widely from year to year, although it remained remarkably constant from 1948 through 1958, ranging from $4.99 per ton in 1948 through $4.50 in 1955 and $5.08 in 1957 to $4.86 in 1958. Since 1958 the average value has declined each year, having reached $4.39 per ton in 1963, the lowest level since 1947. For the 6 years ending 1963, the average value dropped 11½ cents per year. The main reason for these declines, even though labor and other costs have increased during the last period, is increased productivity and competition with other fuels.

There are wide variations in the average value f.o.b. mines among States and counties. Mining conditions, the quality of coal, the distance to markets, the method of transportation, and the competitive situation in the energy market largely explain these variations. The same factors also cause wide differences in costs and prices among producing companies. For example, the principal price factor above f.o.b. mine values is cost of transportation. For rail shipments it amounts to some 74 percent of the f.o.b. mine price. Those producers who are favored by circumstances often have a stabilizing influence on the market.

Such factors as excess capacity and production strongly influence market prices. Both encourage strong intraindustry competition, certain price instability, and lower profits than otherwise might be available. As little coal is stored at producers' facilities, particularly at rail-shipping mines, and as producers generally must dispose of all their sizes, both prepared and resultant, if they are to stay in operation, coal must move into the market within a reasonable time after production. Mines sometimes produce too much of the resultant sizes and dispose of them at prices that disregard production costs. These surpluses can have a depressing effect on prices quite out of proportion to the amount of such coal available.

The shift in emphasis from domestic to industrial uses for coal has brought about some fundamental changes in coal sizes which, in turn, have affected the economics of the industry. Whereas in past years the large market for domestic sizes of coal carried premium prices, and therefore the major share of financial return to the industry, the present and future market will be preponderantly for industrial sizes. Because of competitive pressures, the coal industry has not been able fully to recast its pricing system to match the heavy shift to industrial sizes and thus to bolster its tenuous margin of profitability, nor does it have the flexibility of competitive fuels industries of spreading its pricing pattern over a multiplicity of products.

TAXES

Federal taxes paid by the bituminous coal industry vary with the profitableness of the industry. For more than a decade prior to 1940 the industry operated at a deficit. In 1961, the latest year for which figures are published, and in which 403 million tons were produced, the bituminous coal industry paid $26 million in taxes, and profit after Federal taxes amounted to $31 million. Bituminous coal producers, when computing Federal income tax, are allowed a percentage depletion deduction calculated at 10 percent of gross income from the producing property, but not more than 50 percent of the net income from such property.

TRANSPORTATION

Almost three-fourths of all coal leaves bituminous mines via railroads at rates that add

nearly 74 percent to the cost of the coal at the mines.

Railroads have been the principal means for shipping bituminous coal since their development. In recent years this method of transporting coal has declined appreciably owing largely to increased movement by water and truck from the mines to final destinations. Approximately 40 to 87 million tons of coal is dumped annually at Atlantic coast tidewater piers and transported by water to ports in the United States or exported overseas. In the past decade a range of from 44 to 58 million tons annually has been dumped at lower Lakes Erie, Ontario, and Michigan ports and transported by water to the West North Central States, New York, and Canada. Some of this coal is transshipped by rail or truck to final destination.

Motor trucks for transporting coal appeared immediately after World War I but were not an outstanding factor until the late 1920's. By the middle 1930's trucks had become an important means of transporting coal from mines not only to final destination but also to tipples, railroad sidings, or waterways for further shipment. The development of bigger and better trucks and improved highways has stimulated the growth of truck shipments to final destinations. As railroad freight rates for coal are not strictly proportional to distance and as freight rates for short hauls are higher than for long ones, trucks are used increasingly for short-haul traffic.

Although some of the earliest shipments of bituminous coal were made by river, the major movement by river awaited the growth of large consumers on water, particularly the steel industry on the Monongahela River near Pittsburgh, and in more recent years the aluminum industry in the Ohio River Valley and the Tennessee Valley Authority installations in the Tennessee River Valley. Although in 1963, bituminous coal was shipped from mines by way of 10 rivers and the Inland Waterway, the largest movement was on the Monongahela River. The proportion shipped from mines by water, including the tonnage trucked to water, has grown from 4 percent of total production in 1933 to 11 percent in 1963. Part of this growth represents increased shipments on rivers other than the Monongahela. Like rail shipments, river shipment is not necessarily to a final destination. A considerable tonnage, particularly in the Cincinnati area, is transshipped from the Ohio River to final destination by railroad or truck.

An important development in shipping bituminous coal has been the trucking of coal from mines to railroad sidings or to waterways for further shipment. This relatively new use of trucks made possible the opening of many small mines and even of larger strip mines.

Some railroad companies have established, while others are planning, significant changes in methods of transporting coal to large consumers. These changes include the unit train and modifications of the unit train concept, in which trains consisting entirely of coal cars move quickly from the mining areas to the consumers' plants, with greatly increased efficiency in the utilization of railroad equipment and sizable reductions in cost. There have been some notable railroad freight rate reductions as a result of these new methods, amounting to as much as $1.50 per ton in some cases. The expansion of these concepts will enhance coal's competitive position in important energy marketing areas.

Because of the importance of the cost of transportation, pipeline transmission of coal in water has been developed. The Consolidation Coal Co. constructed a 108-mile coal pipeline from a mine in eastern Ohio to the East Lake powerplant of the Cleveland Electric Illuminating Co. near Cleveland. The $13 million pipeline carried 7 million tons of coal slurry before it ceased operation on a standby basis in May 1963 after railroads made sharp cuts in coal freight rates.

Technological advancement in the long-distance transmission of electric energy continues to result in more large-scale electric generating capacity near or at mine sites.

RESEARCH

Every country in which extensive deposits of coal occur is interested in the effective utilization of these valuable natural resources and is, therefore, conducting a variety of programs geared toward the realization of this objective. In each of these countries there are a variety of government, industrial, university, and/or private organizations conducting research programs on the properties of coal, its production and preparation, utilization as a fuel, and conversion to other forms. The interest, scope, and emphasis on particular investigations are primarily influenced by national conditions, current markets and anticipated needs, as well as the facilities of each research organization.

In the United States there are a variety of laboratories engaged in coal research programs. The Department of the Interior is responsible for more than one-half of the effort in this area, about equally divided between the Bureau of Mines and the Office of Coal Research.

One of the primary functions of the Bureau of Mines is to improve the Nation's ability to meet the energy needs of an expanding economy and

to insure the Nation's security. Within the framework of this objective, the Bureau's projects in coal research and development serve to: (1) increase efficiency and economic development of the industry, including new uses, (2) conserve resources through prevention of waste, (3) investigate mineral fuels belonging to or for the use of the United States, and (4) improve health and safety conditions in the mineral industries. Efforts to realize these objectives involve a variety of coal studies, ranging from fundamental research through development of processes and products. The diversity of problems under investigation by the Bureau can be illustrated by the programs now underway in the Bureau's laboratories, located in important coal-producing centers. For example, the Bureau of Mines laboratories in Pittsburgh and Bruceton, Pa., are conducting programs such as those on coal mining, health and safety, analysis, preparation, combustion, carbonization, conversion to liquid and gaseous fuels, stream pollution, and fundamental studies; in Morgantown, W. Va., on the coal-fired gas turbine and low-temperature tar; at Denver, Colo., western coals investigations including carbonization; at Grand Forks, N. Dak., lignite investigations; at Seattle, Wash., preparation; at College Park, Md., sampling, boiler-water research, and fuel economy service; at Juneau, Alaska, resources studies; and sampling and analysis at Anchorage, Alaska.

The Office of Coal Research undertakes research which holds the greatest potential promise for achieving benefits to the coal industry in new production and markets. Its research, all of which it contracts with outside organizations, covers many disciplines including mining, combustion, conversion processes, and economic and marketing research.

Apart from the Department of the Interior activities in coal research, there are a large number of organizations conducting programs directly related to and supplementing the Bureau's activities in each of the broad areas previously mentioned. Research on coal properties, and studies designed to extend the information available on U.S. coal reserves are being conducted by university and State geological laboratories, such as Illinois State Geological Survey, Ohio Geological Survey, Ohio State University, Pennsylvania State University, and West Virginia University. The production, preparation, and utilization of coal as a fuel are of primary importance to industry and are the objects of study by private and industrial organizations, as well as by university and State laboratories, with many of the latter programs sponsored or supported by industrial groups. In addition to the organizations cited above, interesting and important programs are being conducted by Bituminous Coal Research, Inc., and universities and private concerns in various parts of the country. The variety and scopes of such investigations, and the names of the particular organizations conducting such programs are described each year in a review published in the coal press.

In European countries, coal research programs are administered primarily by government research organizations. The activities of these organizations reflect in scope those of the Federal Bureau of Mines but are directed primarily towards the application of new tools or techniques to local reserves and economic conditions. Thus, the variations in coal quality and availability from country to country as well as the industrial economy of each country are reflected in the emphasis on and type of programs conducted by the counterpart organizations abroad.

In Western Europe, the United Kingdom conducts the largest and most diversified program of coal research. In Great Britain and the Commonwealth Territories, considerable attention has been directed to the exploitation of thinner seams than are mined in the United States and the utilization of fine and low-rank coals, such as lignite. In addition to and related to these investigations, a variety of programs concerned with the advancement of knowledge on the fundamental properties and structure of coal, coal mining (including health and safety), sampling and analysis, preparation, combustion, gasification, and hydrogenation are in progress. As in the United States, attention has also been directed to the possibility of converting coal to liquid and gaseous fuels and plants designed to evaluate the potential application of the Fischer-Tropsch and other processes have been constructed and operated.

In France, the Netherlands, and West Germany, research programs on coal also closely parallel in scope the programs and interest of the Bureau of Mines and other U.S. research organizations.

Cerchar (Centre d'Etudes et Recherches des Charbonnages de France), in France, and Inichar (Institut National de l'Industrie Charbonniere), in Belgium, are the organizations responsible for the greatest effort in coal research in each of these countries, and could also be likened, in scope and interest, to the Bureau of Mines. As in the United States, a number of universities in each of these countries are also conducting specialized research programs on coal. In West Germany, the Steinkohlenbergbauverein conducts the largest number of programs, which is supplemented by the activities of other research organizations and university laboratories.

In the U.S.S.R. and satellite countries, in

India, mainland China, and Japan, research programs administered by government organizations are broad in scope and cover each area described earlier. Of these countries, the U.S.S.R. is probably the most active and has the largest integrated program related to the development of its coal industry. Much emphasis has been placed on the development of new mining equipment and methods and new applications for coal. A concerted effort has been made in the U.S.S.R. to increase productivity, to insure maximum exploitation, and to utilize reserves which, in this country, would be considered uneconomical. Thus a large-scale program for the underground gasification of coal, abandoned on the basis of economics by research organizations in other countries, is still being pursued in the Soviet Union. Other programs in the U.S.S.R., and each of the other countries mentioned, parallel those of the United States.

OUTLOOK

Although the production of bituminous coal and lignite dropped seriously after the post-World War II period of economic rehabilitation and coal's share of the total energy market declined markedly, it reached a turning point in 1961, after which output started an upward trend.

Coal remains as the major supplier of industrial energy, principally because of the increased consumption of coal for steam generation at electric power generating plants. It is indispensable to industrial expansion in national emergencies.

Although future coal production will depend in great part on the degree of availability and consumption of oil, natural gas, and nuclear energy, it is believed that coal has reached, and passed, its lowest point, and that the national economy is undergoing a transitional period in which the demand for all kinds of energy will increase greatly. Our population continues to grow rapidly, and per capita energy requirements are advancing. Business and industry should expand accordingly. The gross national product (the total national output of goods and services) is increasing at about 4 percent per year, and the tremendously accelerating growth of electric power continues unabated. All of these factors point to a considerable expansion in the steel industry, which may be reflected in an increased demand for coke. Continuing improvements in coal technology should result in further reductions in costs of production and increased efficiencies of utilization. There are certain limitations in the sources of competing fossil fuels to supply the expanding energy demand. It is expected that new uses for coal will be found in the hydrogenation, gasification, gas synthesis, and carbonization processes, and in the production of nuclear fuels. In view of these and other factors, it has been forecast that the demand for energy will be so greatly expanded that yearly coal production may reach 775 to 800 million tons within the next 15 years.

PROBLEMS

During times of intense downward pressures on prices, high maintenance costs of idle facilities, and efforts to avoid loss of investments force coal mining companies to continue operating while anticipating a change to better conditions, even though income from sales may be below costs of production; under these conditions operations are maintained only by using up capital.

The pricing of coal is restricted by costs of production and competition with other fuels. Coal does not enjoy the flexibility of some competing fuels for spreading its prices over a multiplicity of products for the reason that coal is a singular product. The importation of other fuels poses some special competitive problems for coal.

The principal problem in relation to coal output and consumption currently and for the future is the development of means to enable coal to compete more favorably with oil, natural gas, and nuclear energy. The basic challenge is to develop advanced technology for further reducing costs of coal production and transportation and to develop methods of handling and burning coal that will provide increasing efficiencies and greater convenience in the use of coal and in the disposal and utilization of its waste products.

Improvements in and new methods of mining are needed to permit extraction of coal at lower cost, with increased safety to the workers, and with consideration of conservation principles and objectives. Effective degasification of gassy mines ahead of mining will relieve a hazard to the mining crews and a major retardant to the continuity of mining operations. Nothwithstanding improved safety practices and requirements, roof falls, the formation and ignition of coal dust, and other hazardous conditions associated with underground mining result in serious accidents, deaths, and losses each

year. Acid mine water drainage from worked-out mines, or sections of mines above the drainage level, is a serious water-pollution problem.

Increased mechanization in the extractive and preparation processes has resulted in the output of finer-sized materials with greater quantities of associated impurities. The mining and supplying of coals that are acceptable for power plant, metallurgical, or other uses imposes a variety of problems. In many cases, more intensive preparation and careful blending of coal are required to produce coals of comparable quality to that used in the past. Current methods of dewatering and thermal drying are relatively expensive. Large quantities of potentially valuable products are lost with the washery refuse and effluents from preparation plants, especially fine coals that cannot be salvaged economically from the waste water. These losses may increase with the expansion of production and will require the development of effective disposal and utilization methods as lack of adequate disposal areas and enforcement of air and steam pollution ordinances curtail current discharging practices.

Because of the increased availability and utilization of petroleum and natural gas, bituminous coal and lignite consumption in the United States has declined from the war-period peak, and there have been some significant shifts in the pattern of utilization. There have been continuing losses in bituminous coal shipments to railroads, retail dealers, bunkers (foreign and lake vessels), and steel and rolling mills (excluding coking coal). However, on the plus side coal consumption by electric power utilities has increased steadily and significantly, and as demands for electric energy continues to grow the increased use of coal by public utilities seems assured. Coal consumption at general industrial plants has been on the increase during the last few years. One of the newer threats to coal is the use of nuclear energy for the generation of electric power. To maintain optimum efficiency of boiler equipment, problems relating to stack-emission and mineral deposits on the convection surfaces of utility steam boilers, which reduce efficiency and limit capacity, remain to be adequately solved.

The emission of air pollutants from coal combustion equipment is a problem of increasingly greater importance. The emission of SO_2, formed when sulfur containing fossil fuels are burned, is of special concern to large cities. One such city has limited the permissible sulfur content of fossil fuels burned within its jurisdiction. There are indications that other State and local governments will enact laws or ordinances designed to minimize air pollution. The Federal Government, under the auspices of Public Health Service is charged with administering the "Clean Air Act of 1964." It is widely recognized that laws by themselves are not sufficient to solve the air pollution dilemma. Industry, as well as the Federal and several State Governments, are conducting research projects to find economical means of solving the problem of increased air pollution which is a result of our increased energy needs.

Transportation costs constitute a significant portion of the price of coal to consumers. To reduce freight costs, there have been sizable shifts to river and truck transportation. The use of unit-trains, which is a relatively new concept in rail transportation, holds great promise in reducing coal freight costs for purchasers or to points using large quantities of coal. In addition, the railroad industry is conducting research on other innovations in coal transportation, including the integral train. These will be very long, special trains of new, larger type cars, for which special types of loading and unloading facilities will be used. Through the substantially increased efficiencies expected, further reductions in coal transportation costs are anticipated.

Extensive application of pipeline transmission of coal would be a significant development. Justification of the costs involved are limited, however, by the need for large-volume coal production and use. Another means of alleviating the problem of coal transportation costs is the long-distance transmission of electricity from generating plants at or near mines, often referred to as coal-by-wire.

New large-scale uses of coal need to be developed. The markets for chemicals, and for gaseous and liquid fuels could provide outlets for substantial quantities of coal. The processing of coal for the independent production of such chemicals and fluid fuels is now uneconomic, however, so that it cannot yet compete on a cost basis with conventional supplies of these products. The development of new, large-scale markets for coal could be realized if the economics of the following processes, all requiring additional research, were modified by adequate new technological developments: (1) production of liquid fuels and chemicals by rigorous hydrogenation of coal; (2) production of organic chemicals by mild hydrogenation of coal; (3) production of liquid fuels and chemicals from water gas; (4) complete gasification of coal by nuclear energy, or alternatively, by conventional reaction with oxygen and steam for making high Btu gas, liquid fuels, and chemicals; (5) improvements in space-heating technology to expand the use of the coal for this purpose.

BORON

By William C. Miller [1]

IN THE 13th century borax was imported into Europe from Asia for use as a precious-metal flux. Later Italy and South America became the leading producers of borax, which was used chiefly for medicinal purposes. The output of boron minerals in the United States started in 1864. Early production was characterized by the recovery of small quantities of borax from the beds of dry saline lakes. Later the mining of colemanite deposits became important. Today the United States furnishes the bulk of world production from deposits of sodium boron minerals. Sedimentary deposits of borax (tincal) and kernite (rasorite) occur in the Kramer district near Boron, Calif. Borax also occurs in a dry lake deposit at Searles Lake, Calif. Minor quantities of calcium borate minerals, colemanite, and ulexite are produced from bed-type deposits.

Boron minerals are mined by open-pit methods at Boron, Calif., and refined by crystallizing from a hot water solution. At Searles Lake borax is recovered from brines by evaporation and crystallization methods.

Reserves of boron minerals at Boron and Searles Lake, Calif., have been estimated to be sufficient for many years at present rates of depletion.

Boron and boron compounds have numerous uses, including applications in glass, ceramics, welding compounds, soaps and detergents, plasters and paints, starches, fertilizers, steel, nonferrous metals, atomic reactors, radio tubes, solar batteries, abrasives, refractories, chemicals, plastics, motor fuel, antifreeze, insulation materials, adhesives, drugs, and cosmetics.

Boron minerals are relatively inexpensive; however, transportation is a large item of the cost. In 1963 the cost of granular borax at the works was $50 per short ton, whereas the price at the warehouse in New York City was $95 per short ton. Elemental boron, which is costly to produce, is finding a larger market.

Boron minerals and compounds are exported from the United States to many countries. Very small quantities of special boron compounds are imported into the United States.

Much research on boron and boron compounds has been conducted by industry and the Government. The Bureau of Mines is conducting programs on the production and properties of high-purity elemental boron and has studied boron mining problems. Industry is concentrating research on boron polymers, epoxy-boron fibers, and glass-fiber textiles.

The outlook for the continuing growth of boron markets is good. Increased production facilities have been undertaken by the principal producers, and increased consumption of boron products can be anticipated. New products will be made commercially available as a result of achievements in research.

Most of the problems involving boron will stem from marketing rather than from production. The use of boron minerals is inhibited somewhat by transportation costs and the remoteness of production areas from markets.

BACKGROUND

Boron compounds were known and used for many centuries before the element boron was discovered. Three chemists, Joseph Louis Gay-Lussac and Louis Jacques Thenard of France and Sir Humphrey Davy of England discovered the element almost concurrently in June 1808 (*7*, *15*).[2]

The earliest recorded use of borax, the most important compound of boron, was by Asian artisans in the welding and brazing of precious metals and the glazing of pottery. The importation of borax into Europe from Tibet in the 13th century was the start of the modern boron industry. In the middle of the 18th century sassolite was discovered in the hot springs of Tuscany, Italy. Starting about 1828, recovery of boric acid from these hot springs supplied

[1] Commodity specialist.

[2] Italicized numbers in parentheses refer to items in the list of references at the end of this chapter.

much of the world's requirements. Borax mining began in Chile in 1852, and that country became the principal producer. The chief use for borax during this period was for pharmaceutical purposes.

In 1856 borax crystals were discovered in the mud of a small saline lake in Lake County, Calif. Production of borax from saline lakes in northern California started in 1864 and continued for 10 years. Ulexite was found in quantity on the arid lake beds of Nevada in 1870. During the 1870's and 1880's ulexite and borax were recovered from Columbus Marsh and Teel's Marsh in Nevada and from Searles Lake in California, which caused the northern California operations to be discontinued. From 1883 to 1889 borax was obtained from Death Valley (*20*, *21*).

The greater part of the world's supply of borax came from the colemanite deposits in the Calico Mountain district, Calif., between 1887 and 1907. When these deposits were worked out, production was shifted to the Furnace Creek district, adjacent to Death Valley. The colemanite and lake deposits of this district were the principal source of borax from 1915 to 1926.

Since 1927 the rich deposit of borax and kernite ore in the Kramer district of Kern County, Calif., has been the world's principal source of boron (*16*).

Production of borax from Searles Lake, Calif., started in 1874 and continued until about 1893, when playa operations were supplanted by colemanite mining. In 1908 operations at Searles Lake were started again, but output was sporadic. Since 1916 production of borax and various coproducts from Searles Lake brine has been continuous.

When originally imported into the United States from England, borax was a high-priced commodity, used chiefly for pharmaceutical purposes. By 1892 the price was lowered substantially so that borax was used for many other purposes. The most important of the 50 uses listed at that time were as an antiseptic, a meat preservative, soap and cleansers, and an ingredient in tooth and face powder, process used in printing calico dresses, varnish, plaster paint, fireproofing material, and insecticides.

SIZE, ORGANIZATION, AND GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

Four domestic firms produced boron minerals in 1963 from bedded and vein deposits and from natural brines. The entire output came from southern California. Total production was 700,183 short tons valued at $54 million. The principal producer, Pacific Coast Borax Division of United States Borax & Chemical Corp., produced kernite (rasorite) and borax (tincal) from a bedded deposit in the Kramer district near Boron, Calif., and colemanite in Inyo County, Calif. The second largest producer, American Potash & Chemical Corp., recovered a substantial quantity of borax from the brine of Searles Lake at Trona, Calif. The West End Chemical Division of Stauffer Chemical Co. recovered borax from the brine of Searles Lake. Kern County Land Co. mined colemanite in Inyo County, Calif.

Other deposits of boron minerals occur in Nevada, Oregon, and California but are not mined at present.

In addition to the producers of boron minerals, there are approximately 50 companies that produce a wide variety of boron products and about 20 companies that produce boric acid.

Outside the United States, Turkey is the leading non-Communist boron mineral producing country (*12*, *13*). Three operating companies produced colemanite from deposits in western Turkey. Etibank, a state mining enterprise, is the principal producer. In 1963, Etibank produced about three-fourths of the total output.

Boric acid is produced from steam vents at Tuscany, Italy, by a state-controlled firm.

In South America the boron production comes from ulexite deposits in Argentina and Chile. Cía Productora de Boratos and Boroquímica Ltda., are the leading producers in Argentina. Borax Consolidated, Ltd., is the only producer in Chile.

DEFINITION OF TERMS, GRADES, SPECIFICATIONS, AND PROPERTIES

Elemental boron has an atomic weight of 10.82, melting point of about 2,300° C and boiling point of 2,550° C. Boron is produced in two forms, amorphous and crystalline. The amorphous variety is a black-to-greenish-yellow powder, whereas the crystalline form is a brittle, shiny, hard solid. Boron is marketed in grades of 90 to 92, 95 to 97, and 99-plus percent purity.

Borax ($Na_2B_4O_7 \cdot 10H_2O$) is purified to grades of 99.5 percent and marketed as decahydrate and pentahydrate. An anhydrous form of borax is also marketed. Borax is available in commercial or technical, U.S.P., and special-quality grades. It is sold in crystalline, granular, or powder form.

Boric acid (H_3BO_3) is manufactured as colorless, odorless crystals. It is sold as commercial or technical, U.S.P., and special-quality

grades. It is available in crystalline, granular, or powder forms.

Boric oxide is a hard, brittle, colorless, transparent glass. It is marketed in powder or granular forms.

Ferroboron is a boron iron alloy containing 0.20 to 24 percent boron. Boron alloys are marketed in a number of grain sizes.

Diborane (B_2H_6) is a gas with a heating value of 31,200 to 33,300 Btu per pound. Pentaborane (B_5H_9) is a liquid with a heating value of 29,000 to 30,400 Btu per pound. Decaborane is a solid with a heating value of 28,200 to 29,300 Btu per pound.

Boron nitride is manufactured as a white, greasy, amorphous-to-flaky solid. It crystallizes in thin hexagonal plates, similar to graphite. Boron nitride has an electrical resistivity of 1,900 ohms per centimeter at 2,000° C and a very low thermal conductivity. It can be obtained in grades of less than and greater than 98 percent purity.

TECHNOLOGY

Many known minerals contain boron, but only a few are commercially valuable as a source of boron. The principal boron minerals are borax (tincal), $Na_2B_4O_7 \cdot 10H_2O$; kernite (rasorite), $Na_2B_4O_7 \cdot 4H_2O$; colemanite (borocalcite), $Ca_2B_6O_{11} \cdot 5H_2O$; ulexite (boronatrocalcite), $CaNaB_5O_9 \cdot 8H_2O$; priceite (pandermite), $5CaO \cdot 6B_2O_3 \cdot 9H_2O$; boracite (stassfurtite), $Mg_7Cl_2B_{16}O_{30}$; and sassolite (natural boric acid), H_3BO_3.

The sodium borate minerals borax (tincal) and kernite (rasorite) constitute the bulk of production in the United States. A small quantity of colemanite and ulexite is also mined. Sodium borate mineral deposits on the public domain can be acquired under the mineral Leasing Act of February 25, 1920. Other minerals, such as colemanite, are open to exploration and purchase under the mining laws of May 10, 1872.

The borate deposit in the Kramer district of California is a large, tabular, irregular mass of bedded crystalline sodium borates ranging from 80 to over 250 feet in thickness. Borax, locally called tincal, and kernite are the principal minerals. Shale beds containing colemanite and ulexite lie directly over and under the sodium borate body (*16*, *20*).

The ore, mined by open pit methods, is blended and crushed to produce a minus ¾-inch refinery feed of nearly constant boric oxide (B_2O_3) content. Weak borax liquor from the refinery is mixed with the crushed ore and heated nearly to boiling point in steam-jacketed tanks to dissolve the borax. Before the concentrated borax liquor goes to a series of thickeners, the solution passes over a vibrating screen to separate the insoluble rock and clay particles. Concentrated solution from the thickeners is filtered and pumped to vacuum crystallizers. One of the crystallizers produces borax pentahydrate, and the other produces borax decahydrate. Crystals are separated from the slurry of borax pentahydrate or decahydrate by automatic centrifuges. From the centrifuges, the crystals are fed to dryers to remove surface moisture. The borax crystals are stored prior to sale or shipment to other divisions for production of anhydrous borax, boric acid, boric oxide, and specialty products.

The Searles Lake Deposit, in the northwest corner of San Bernardino County, Calif., covers about 34 square miles and contains two crystalline salt beds separated by an impervious mud seam 10 to 14 feet thick. The upper crystalline bed ranges from 25 to 40 feet in thickness and the lower bed from 70 to 90 feet. Saturated brine, containing about 35 percent dissolved solids, fills about 45 percent of the volume of each salt bed. The lower salt bed brines contain the higher concentration of borates (*8*, *19–21*).

Two processes are used to recover borax from the brines of Searles Lake. American Potash & Chemical Corp. uses an evaporation process to treat the upper bed brines and a carbonation process to treat the lower bed brines. West End Chemical Division of Stauffer Chemical Co. uses a carbonation process. The operations of the carbonation processes used by the companies are similar.

Most of the borax produced from the Searles Lake brines is by the evaporation process. In this process, the brine goes to the potash plant where sodium chloride (NACl) and burkeite ($2Na_2CO_3 \cdot 3NaSO_4$) are crystallized and separated from the liquor containing potash (KCl) and borax ($Na_2B_4O_7 \cdot 10H_2O$). By cooling the liquor rapidly in special crystallizers, the potash is crystallized and filtered from the solution. The chemistry of the process is complex and care must be exercised to prevent the boron from being crystallized with the potash. Mother liquor from the potash plant and borax (decahydrate) from the carbonation plant is sent to the borax plant. The liquors are fed into large crystallizers containing a thick bed of seed crystals to crystallize the pentahydrate of borax. From the crystallizers the sludge stream is sent to a liquid cyclone and to crude borax filters. The solids from the filters are washed, repulped, and redissolved before being sent to vacuum crystallizers where high-purity borax (decahydrate) or pentahydrate is formed. After the products are dewatered and dried, they are screened to the desired fractions.

In the carbonation process, brine from the lower salt bed is fed into the top of primary carbonation towers where the brine is contacted by carbon dioxide gas which enters the bottom of the towers. Boiler flue gas is used by American Potash and gas from a limekiln is used by West End Chemical. From the primary towers the slurry is sent to secondary carbonation towers to complete the carbonation. Sodium bicarbonate filters remove the soda ash, and the filtrate is blended with additional raw brine before the solution enters vacuum crystallizers where decahydrate borax is crystallized. The slurry containing borax and some sodium bicarbonate is sent to the evaporation plant in the American Potash process. In the West End Chemical process, the slurry is further refrigerated to crystallize the sodium sulfate.

Boron carbide (B_4C) is produced by reacting boric oxide (B_2O_3) with coke in a carbon resistance furnace at 2,600° C. The product is about 99 percent B_4C.

Elemental boron has been produced by fused-salt electrolysis, hydrogen reduction and decomposition of boron compounds, reduction of boron halides with active metals, and reduction of other boron compounds with active metals (*4*, *10*).

Commercial quantities of 95- to 99-percent-pure boron are produced by passing a mixture of boron trichloride gas and hydrogen over a series of electrically heated graphite rods in a resistor furnace. Layers of boron carbide and elemental boron are deposited on the rods. At the conclusion of a furnace run the boron layers are removed from the rods and the elemental boron is separated from the adherent graphite and boron carbide by sorting. Boron carbide, containing 80 to 90 percent boron, is obtained as a byproduct of the process (*6*, *14*). Relatively large amounts of elemental boron of the same purity can be prepared by a three-step process. First, a crude product is produced from the reduction of boron trioxide with magnesium by thermite reaction. The product is roasted with a fluoride and is subsequently leached with water and acids (*22*).

Another method of producing commercial quantities of 99-percent-pure elemental boron consists of electrolyzing a fused bath of potassium chloride or fluoride, potassium fluoborate, and boron oxide in an electrolytic cell. The cell consists of an externally heated crucible of graphite, which serves as the anode, and a low-carbon iron plate mounted for vertical movement into and out of the bath. Electrolysis of the fused mixture at 650° to 1,000° C deposits high-purity boron of the cathode.

USES

Boron compounds are used extensively in the glass and ceramics industries, where their low melting points and excellent fluxing properties are utilized. These properties also are advantageous in brazing, welding, soldering, and refining.

Borax or boric acid is widely used in soaps, cleansers, and detergents because of its easy solubility in water and excellent water-softening properties. Its mild alkalinity in water and its germicidal properties make it useful in toothpaste, mouthwash, and eyewash. Water solutions of borax are used in dyeing leather and textiles, in cleansing hides and skins, in plasters and paints, to prevent mildew and give high gloss to starches, and to prevent mold on leather, textiles, and citrus fruits. In agriculture, borax is added to fertilizers to supply boron as an essential plant nutrient. Boron compounds are also used to control weeds.

Boron compounds are added to alloy steels to increase hardenability. Some elemental boron is used as a deoxidizer in nonferrous metallurgical reactions, as a grain refiner in aluminum, as a thermal neutron absorber in atomic reactors, in delayed action fuses, as an ignitor in radio tubes, and as a coating material in solar batteries.

Compounds of boron such as boron carbide, titanium boride, and tungsten boride are among the hardest substances known. Boron carbide is used in the manufacture of abrasion-resistant parts of spray nozzles, bearing liners, and furnace parts; in the atomic energy field as nuclear reactor control elements and radiation shields; and as an abrasive for ultrasonic grinding and drilling. Boron nitride is useful as a thermal insulator and as a mold lubricant in glass manufacture. Titanium boride is available in commercial quantities but its use is not widespread.

Increasing use is being made of boron trichloride as a catalyst in silicone production, as a synthesis intermediate, and as an extinguishing agent for magnesium fires. Boron trifluoride is used as a catalyst for many organic reactions such as polymerizations, esterifications, and alkylations.

Organic boron compounds such as borate esters are finding greater use as dehydrating agents, synthesis intermediates, special solvents, sources of boron for catalysts, plasticizers, and adhesion additives for latex paint, and fire retardants in plastics and protective coatings. An organic boron compound is used as a motor fuel additive to suppress preignition firing.

Boron compounds such as diborane (B_2H_6), pentaborane (B_5H_9), decaborane ($B_{10}H_{14}$), and alkyl boranes are potential jet and rocket fuels.

BYPRODUCTS AND COPRODUCT RELATIONSHIPS

American Potash and West End Chemical obtain a number of coproducts or byproducts at their borax operations. Soda ash, salt cake, potash, sodium chloride, bromine, and lithium compounds are extracted from the Searles Lake brine.

ALTERNATE MATERIALS

There are few substitutes for boron minerals and compounds, inasmuch as they are inexpensive and plentiful. Soda ash and detergents are used as alternate materials in cleaning products.

RESERVES

Estimates were made with due consideration for anticipated increased production rates of the reserves of boron minerals available in the two major domestic sources. These reserves can supply the needs of the industry for more than a hundred years. Measured and indicated reserves of the sodium borate deposit at Boron, Calif., contain over 100 million tons of borax. Indicated reserves of the borax content in the brines and crystalline beds of the Searles Lake deposit total about 150 million tons. In addition to the reserves of the major deposits, the minor deposits of sodium borate could supply an appreciable tonnage of borax.

As production from the domestic deposits of bedded calcium borate practically ceased in 1927, very little exploration has been done since that date to determine the resource potential of these deposits. Some of the deposits are extensive and probably contain appreciable tonnages.

In South America borate deposits occur in Argentina, Chile, Bolivia, and Peru. All of the deposits are primarily sodium borates, except for one bedded deposit in Argentina where the principal ores are calcium borates. Millions of tons of reserves have been reported for the borate deposits, but no data have been published to substantiate these claims.

The measured and indicated reserve of the borate deposits, primarily colemanite, occurring in Turkey is 15 to 20 million tons. Continuing exploration over the past few years indicates that the deposits are extensive, and the potential resource could be substantially larger than the reserve.

Reserves of boric acid occurring in the steam erupting from hot springs at Tuscany, Italy, are difficult to determine because of the nature of the deposit and the uncertainty of the boron source.

The Stassfurt-type deposits of West Germany have small reserves of magnesium borate minerals.

CONSERVATION PRACTICES

Boron mineral producers are adopting conservation practices to lower costs and extend the life of deposits. Conversion of Pacific Coast Borax's mine from underground to open-pit mining methods and the adoption of new procedures for concentrating the ore will permit the mining of larger quantities and the utilization of lower grades of ore. American Potash is employing a new process that produces boric acid from weak brines which cannot be used in conventional processes. Potassium sulfate and sodium sulfate also are produced by the new process.

SOURCES OF STATISTICAL INFORMATION

The Bureau of Mines annually collects and publishes figures on the quantity of boron minerals and compounds sold or used by U.S. producers. The Bureau also compiles figures on imports and exports of boron minerals and compounds from data accumulated by the Bureau of the Census, U.S. Department of Commerce. Information on world production is also obtained from Foreign Service dispatches sent to the U.S. Department of State by its emissaries in foreign countries.

PRODUCTION, CONSUMPTION, AND TRADE

The United States produces more than 85 percent of the world output of boron minerals. Production of boron minerals and compounds (as measured by sales) is shown in table 1. American Potash completed a 35-percent increase in its production capacity in 1962.

Production of boron minerals in Turkey during 1963 totaled 97,100 tons. Most of the Turkish exports are shipped to European markets. In 1963 Italy produced 567 tons of boric acid. Argentina produced 26,691 tons of borax of which 5,500 tons were exported, mainly to Brazil. Production of ulexite in Chile in 1963 totaled 3,286 tons.

Almost half of U.S. production of boron minerals and compounds is exported. In 1963 West Germany, the United Kingdom, France, Japan, Canada, and the Netherlands received the greater part of boron exports; more than 50 other countries received substantial shipments. Imports of boron commodities into the United States are very small and usually consist of special compounds.

TABLE 1.—*Salient boron minerals and compounds statistics in the United States*

	1954–58 (average)	1959	1960	1961	1962	1963
Sold or used by producers:						
Short tons:						
Gross weight [1]	585, 269	619, 946	640, 591	602, 613	646, 613	700, 183
Boron oxide	255, 891	314, 286	323, 955	313, 104	339, 060	369, 302
Value—thousands	$33, 321	$46, 150	$47, 550	$46, 936	$49, 336	$54, 981
Imports for consumption:						
Short tons	[2] 1, 066	91	74	15	15	17
Value—thousands	$148	$174	$202	$52	$51	$58
Exports:						
Short tons	224, 402	253, 674	300, 606	269, 271	292, 264	338, 912
Value—thousands	$15, 660	$21, 047	$25, 576	$23, 212	$24, 736	$27, 519
Consumption, apparent: Short tons	361, 933	366, 363	349, 059	333, 357	354, 364	361, 288

[1] In 1954 gross weight reported included a higher proportion of crude ore to finished products than in 1955–63.
[2] Imports for 1957 include a higher proportion of crude ore to refined products.

According to the Tariff Schedules of the United States (TSUS) which went into effect on August 31, 1963, crude or unmanufactured borax, borate of lime, borate of soda, and other crude and unmanufactured borate materials are free of import duties. Refined sodium borate or borax has an import duty of one-eighth of a cent per pound. Boric acid carries a rate of 5 cents per pound. Boron carbide is rated at 6.25 percent ad valorem. Ferroboron and manganese borate are rated at 10 percent ad valorem. Only small quantities of boron compounds are imported.

STRATEGIC CONSIDERATIONS

In the United States there are large proved reserves of boron minerals, and the possibilities of finding new deposits or extensions of known deposits are good. This country will be self-sufficient for many years at present rates of depletion.

On the other hand, the concentration of the bulk of boron mineral production in a small area approximately 100 to 150 miles from the Pacific coast presents a supply problem in wartime.

GOVERNMENT PROGRAMS

Boron has a great variety of uses important to defense, such as a flux in welding and in brazing, in alloys for cutting tools, and for alloying steel. Export shipments of boron minerals and boron compounds must be licensed. Under the provisions of the Mutual Defense Assistance Act of 1951, boron minerals and compounds were placed under export control because they are items of primary strategic significance used in the production of implements of war. On June 30, 1964, Government inventories totaled 67,636 long dry tons of colemanite in the supplemental stockpile. The ore was acquired by the Commodity Credit Corporation from Turkey in exchange for U.S. surplus agricultural products.

PRICES AND COSTS

A century ago, refined borax was imported from England at a cost of approximately $1 per pound. From 1864 to 1868 an average of 300 tons per year of refined borax was produced in the United States and sold for 28 to 35 cents per pound. In 1874 the price of refined borax in San Francisco, Calif., dropped from an average of 25 cents per pound to as little as 6.5 cents per pound, although the price rose later to between 11 and 13 cents per pound. Since that time it has declined, owing to the discovery and development of deposits of higher grade minerals.

Borax prices at works have remained stable since 1959. Anhydrous boric acid has held at $335 per short ton in carlot quantities, technical-grade anhydrous borax (99 percent) at $92 per ton in bags and $83 per ton in bulk, and technical-grade granular decahydrate borax (95.5 percent) at $50 per ton in bags, or 2.5 cents per pound, and $43.50 per ton in bulk. Warehouse price in New York for decahydrate borax has been reduced from $103.75 (1959 price) to $95 per ton because of reduced freight rates. Quoted price of borax and some boron compounds is published weekly in the Oil, Paint and Drug Reporter.

In 1963, sodium tetraborate pentahydrate sold for $47.50 per short ton in bulk lots, at works, sodium metaborate tetrahydrate, $104.50; sodium metaborate dihydrate, $155; anhydrous borax, $83; ammonium diborate, $303; and ammonium pentaborate, $196.

During 1963 company brochures listed elemental amorphous boron of 90 to 92 percent

purity at $13 per pound in ton lots and $30 per pound in small lots. The price of high-purity, 99-plus percent boron was listed in the American Metal Market as $70 per pound.

Prices of boron carbide and boron nitride products depend on the quantities and grit size distribution. Fabricated products of these compounds are considerably more expensive.

TAXES

Under the Federal income tax law, boron mineral producers have a percentage depletion allowance of 15 percent of gross income, not to exceed 50 percent of the net income without depletion deduction. Kern County, Calif., levies a production tax on boron minerals based on the value of the tonnage mined. A corporation income tax on net income derived from sources within the State is levied by California.

TRANSPORTATION

As boron minerals are bulk commodities, transportation is a critical factor in distribution and price trends. Boron minerals must be transported for long distances from the production areas in southern California to manufacturing areas in the Eastern United States. In November 1963 the first bulk shipment of borate products was made to Europe.

RESEARCH

Industry and Government have a number of research programs on boron and boron compounds. The Bureau of Mines has done research on hard carbides and borides which involved studies of the production and properties of boron carbides and metal borides and on boron mineral mining problems. Currently the Bureau is studying methods of producing ultrapure boron and determining its properties.

U.S. Borax Research Corp., Anaheim, Calif., a subsidiary of United States Borax & Chemical Corp., and the research laboratories of American Potash and Stauffer Chemical are conducting short-term and long-term projects on research and development programs. Emphasis of these programs is placed on the development of titanium diboride electrodes for use in aluminum manufacture, new organic herbicides and problems caused by Federal regulations pertaining to herbicides, development of boron containing inorganic polymers, boric acid esters, boron hydrides, boron-based epoxy resin curing agents, and diboron compounds. Government-sponsored research programs in several fields of boron chemistry were pursued.

General Electric Co., Lockheed Aircraft Corp., Aerojet-General Corp., General Technologies Corp., and several small companies are engaged in experimental work in the boron-filament and composite structures field. An epoxy-boron fiber was developed by the Air Force Systems Command. The U.S. Navy and the National Aeronautics and Space Administration are sponsoring research on the use of boron in structures.

Research leaders in glass fiber industry are concentrating on developing superior properties in glass-fiber textiles and hollow fibers. The glass wool industry is directing its research toward new end uses and improved production methods rather than new types of fiber.

OUTLOOK

The short- and long-range outlook for continued expansion of the markets for boron minerals is attested to by the extensive expansion programs for increased production capacity undertaken by the principal domestic producers. Sodium borates from the open pit mine at Boron, Calif., and the brines from Searles Lake will continue to supply the greater portion of boron minerals; however, production of calcium borates, especially colemanite, is expected to increase substantially.

Turkish boron producers will increase mine and plant capacities to keep pace with the steadily increasing exports of colemanite to processing plants in Italy, West Germany, and France. Substantial tonnages of minerals and refined products may be exported to certain Communist nations if long-term agreements now being negotiated are concluded.

Argentina, with significant deposits of borax and an extensive reserve, could increase its export trade of boron minerals with other South American countries provided that the price was lowered enough to make it competitive with U.S. borax.

The domestic consumption of boron products is expected to increase. Construction of additional production facilities and processing plants should increase as expanding and additional markets are developed and as improved and new products become commercially available.

Increasingly larger quantities of boron compounds will be consumed by the still-growing markets of the well-established uses, namely, household and industrial cleaners and the glass and ceramics industries. The growth rate of the production of these items is closely alined

780-887 O—65——11

with the growth rate in population and the consumption of expenditure durables.

Continued use of large quantities of boron in agriculture, herbicides, and boric acid esters can be anticipated. Development of new merchandizing methods should result in an increase in the sale of more boron products in these fields.

Encouraging results achieved from application research indicate that additional markets for boron products can be anticipated. High-boron borosilicate glass and boron phosphide have applications in the electronics industry. Production is expected to start on improved glass fibers for the textile and plastic industries and for tire cords. The use of titanium diboride electrodes in the aluminum industry is especially promising. Epoxy-boron fiber could revolutionize the structural building material used in military and civilian construction.

Two boron products that have recently been made commercially available could develop into large markets. Alkyl borate will prevent scale formation on reheated steel. The properties of high-performance resin, the first commercial boron polymer, are high heat resistance, strength, hardness, and electrical resistivity. It is adaptable for electrical insulation.

Export of boron minerals and compounds has grown faster than domestic consumption during recent years and is expected to remain a major factor in the economy of the U.S. boron industry. Although shipments of Turkish boron minerals to Europe will increase, the well-established markets of the U.S. producers should not be adversely affected. Facilities for the handling of bulk shipments by oceangoing ships from the west coast of the United States should offset the Turkish transportation advantage.

Possible imports of Turkish colemanite to the east coast of the United States may cause some concern to the domestic mineral producers. Manufacturers of fiber glass, fertilizer, and certain types of glass would replace the boric acid used in their production processes with colemanite, if an economical supply could be obtained.

Most research will probably be directed toward the development of new and improved boron products; however, new end uses of boron will receive attention.

PROBLEMS

Problems related to the mining of boron minerals are minor at present. The anticipated large long-term growth in consumption of boron minerals will make it necessary to mine lower grade minerals at greater depths. Numerous technologic problems will arise which could limit the production rate and increase the cost of boron materials.

Relatively high transportation cost, due in part to the bulky nature of the minerals and the remoteness of the mines from markets, limits the distribution and utilization of boron minerals.

Technical research is required to enable calcium borate minerals to become economically competitive with sodium boron minerals.

Concentration of boron mineral production in a relatively small area in the United States presents a wartime supply problem. More exploration is required to determine the scope of additional areas that could be mined in event of a national emergency.

Development of additional domestic markets is required to compensate for any loss of foreign markets.

A deterrent to the development of more uses for boron products is the difficulty of applying data obtained from laboratory experimentation to economical commercial processes.

The production and use of toxic and relatively unstable boron compounds may present health and safety problems.

Export controls on boron minerals create problems to the firms and governments engaged in international trade.

BROMINE

By William C. Miller [1]

OCEAN water, brines from saline deposits, and oil-well brines give the United States an inexhaustible source of bromine.

This element is a reddish-brown, volatile, toxic, and corrosive liquid at ordinary temperatures. It is widely distributed in the earth's crust in small quantities and occurs chiefly in natural brines, saline deposits, salt lakes and seas, and the ocean. Bromine is recovered as a coproduct. The 1963 domestic production of bromine compounds totaled 239 million pounds and was valued at $49 million. The United States is self-sufficient in bromine. Additional supplies may become available through programs directed toward the production of fresh water from saline waters.

Short-term consumption of bromine will probably increase; however, long-term demand is uncertain owing to technologic changes.

Problems confronting the bromine industry are—the abundance of supply, the uncertain market for ethylene dibromide, need for more diversified markets, the high price of bromine relative to the price of chlorine, and the need for governmental approval and public acceptance of bromine as fumigant and sanitization agents.

BACKGROUND

Bromine was discovered by Antoine-Jérôme Balard, a French chemist, who extracted it from sea-water bitterns. He published his results in 1826. In Heidelberg, Germany, Carl Löwig obtained bromine from Kreuznach salt-spring liquors and published his results in 1829. In the United States, bromine was recovered from natural brines in 1846 at Freeport, Pa., and in Germany it was detected in 1858 in the salt from the Stassfurt deposits.

SIZE, ORGANIZATION, AND GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

The bromine industry began in 1865 with production from the Stassfurt deposits in Germany. In the United States bromine production started in 1867 as a byproduct of salt production in the Pomerory, Ohio-Hartford and Mason, W. Va., district.

The greater portion of U.S. production has been from well brines in Ohio, West Virginia, and Michigan. Since 1897, except for a 20-year period, 1938–57, Michigan has been the leading bromine producer. Bromine was produced in Ohio until 1951 and in West Virginia until 1961. Bromine production experienced its greatest growth after 1922 when its usefulness in a gasoline antiknock mixture was discovered. In 1924 tests aboard the S.S. *Ethyl* demonstrated the feasibility of recovering bromine economically from the sea. A sea-water recovery plant was built at Kure Beach, N.C., in 1934 and was moved in 1946 to Freeport, Tex. From 1939 until 1958 the bulk of U.S. production of bromine was from sea water.

Annual bromine production in the United States was valued at approximately $49 million in 1963. Slightly over 50 percent of the domestic production is from brine wells, about 35 percent from sea water, and the remainder from oil-well brines and saline-lake brines. Substantial expansion recently completed by two producers of bromine from brines should give the industry sufficient capacity for several years to supply the expected increase in markets.

Bromine is recovered from well brines in Michigan by The Dow Chemical Co., the largest domestic producer, at Midland and Ludington; by the Michigan Corp. at St. Louis and Filer City; by Great Lakes Chemical Corp.; and by Morton Chemical Co. at Manistee. Ethyl-Dow

[1] Commodity specialist.

Chemical Co. extracts bromine from sea water at Freeport, Tex., and Inorganic Chemical Division, F.M.C. Corp., produces bromine from sea-water bitterns at Newark, Calif. Bromine is recovered from oil-well brines near El Dorado, Ark., by Michigan Chemical Corp. and Arkansas Chemicals, Inc. American Potash & Chemical Corp. recovers bromine from saline-lake brines at Trona, Calif.

Bromine is recovered from the Stassfurt deposits of Germany as a byproduct of potash production. In Israel, one of the largest bromide plants in the world extracts bromine from the end brine of potash production from the Dead Sea. Bromine is produced in Japan from bitterns of the sea-salt industry and from brine wells on the Ciba Peninsula. Two sea-water plants furnish bromine for the production of ethylene dibromide in Great Britain. In France bromine is extracted from sea water and potash brines. Italy, India, Spain, and Australia also produce some bromine.

DEFINITION OF TERMS, GRADES, SPECIFICATIONS, AND PROPERTIES

Elemental bromine is marketed in a "purified" grade. Specifications for this grade are—specific gravity at 15° to 20° C, not less than 3.1; bromine, not less than 99.7 percent; iodine, none; and chlorine, not more than 0.1 percent.

Potassium bromide is marketed in technical, U.S.P. (U.S. Pharmacopoeia), C.P. (chemically pure), N.F. (National Formulary), and reagent grades. Potassium bromate is sold in pure (not less than 99.5 percent), C.P., U.S.P., and powder grades. Sodium bromide is sold in grades of C.P., U.S.P., crystalline, powder, commercial, pure, and highest purity. Sodium bromate is available in pure, C.P., and reagent (not less than 99.5 percent) grades. Ammonium bromide is sold as technical, pure, C.P., and N.F.

Specifications for the various grades of bromine compounds are—technical bromine, 99.5 percent pure. Chief impurities are chlorine, traces of moisture, and organic matter. Specifications of the U.S. Pharmacopoeia and the American Chemical Society Committee on Analytical Reagents allow 0.3 percent chlorine, 0.05 percent iodine, 0.002 percent sulfur (0.006 percent SO_4), and no more organic matter in 1 ml than will saturate 50 ml of 5-percent sodium hydroxide solution (*6*)[2]. Chemically pure signifies a minimum of impurities but does not imply 100-percent purity.

Bromine is a reddish-brown, volatile liquid. It is very corrosive and attacks the skin and mucus membrane. The toxicity limit for bromine is one part per million parts of air by volume for an 8-hour workday (*8*).

TECHNOLOGY

Bromine is widely distributed in the earth's crust in relatively small quantities. Few natural bromine minerals are known. It accumulates chiefly in the ocean, salt lakes and seas, and other natural brines in the form of bromide ions and in saline deposits as chloro-bromide crystals.

In the United States, bromine is extracted from brines and bitterns by a steaming-out process and from sea water by a blowing-out process. In both processes four essential steps are employed—(1) treatment with chlorine to oxidize the bromide to bromine, (2) removal of bromine vapor from the solution, (3) condensation of bromine vapor or reacted to form a salt or acid, and (4) purification of bromine.

In the steaming-out process the brine is pumped through a heat exchanger into a packed tower. Chlorine introduced into the bottom of the tower forms hydrochloric acid in the brine, reducing hydrolysis of bromine and increasing process efficiency.

When treating sea-water bittern, concentrated sulfuric acid may be added to reduce alkalinity and minimize hydrolysis of bromine.

The brine continues to a second tower constructed of granite or soapstone and filled with ceramic packing. Steam is introduced at the bottom of the tower, and chlorine is introduced at an intermediate point. Ascending chlorine gas mixes with the hot descending brine, oxidizing bromide to bromine. The bromine is carried from the brine by the steam. Bromine vapor, a little chlorine, and water vapor escape from the top of the tower. A hot bromine-free liquor emerges from the bottom of the tower, is neutralized with lime, and then is pumped to waste through a heat exchanger.

Bromine vapor passes from the tower to a condenser and then into a gravity separator. Noncondensable gases, bearing some chlorine and bromine, escaping from the top of the separator, are returned to the chlorinator. Crude bromine flows through a trap in the bottom of the separator to a distilling column. Here halogenated hydrocarbons are removed, and free chlorine and bromine vapors pass from the top of the separator into a reflux condenser for cooling. Chlorine separated in the condenser is returned to the steaming-out tower. The bromine is purified by a recently developed process that combines physical and chemical treatments. This process has increased the purity of commercially available bromine from 99.80 percent to 99.98 percent. About 95 per-

[2] Italicized numbers in parentheses refer to items in the list of references at the end of this chapter.

cent of the bromine is recovered from the raw brine.

In the blowing-out process sea water is pumped through a rubber-lined pipe to the top of a brick and concrete tower. Two and six-tenths pounds of 10-percent sulfuric acid per ton of sea water is introduced at the base of the pipe to neutralize bicarbonates in the water. This lowers the pH to 3.5, preventing losses of chlorine and bromine by hydrolysis. Chlorine is added at the top of the pipe to free bromine. Air drawn in at the base of the tower passes through wood packing, countercurrent to the descending brine. The air, laden with bromine, passes from the blowing-out tower through an absorbing tower in which halogens are taken up by sulfur dioxide.

Air from the blowing-out tower is mixed with water vapor and sulfur dioxide. The resulting acids are collected and transferred to a steaming-out tower where bromine and chlorine are liberated. The byproduct hydrochloric-sulfuric acid is used for acidification of the raw ocean water (*6*).

Bromine from the steaming-out tower is introduced into a packed reactor for the production of ethylene dibromide. Descending bromine reacts with a rising stream of ethylene gas forming ethylene dibromide with the evolution of heat. The rate of introduction of bromine and ethylene gas is regulated to maintain a temperature in the reaction zone above the boiling point of bromine but below the boiling point of ethylene bromide. The reaction proceeds in a vapor phase while the liquid ethylene bromide formed flows out of the reactor countercurrent to the incoming stream of ethylene gas. Free acids in the ethylene dibromide are neutralized, and the liquor is fractionated in a still to remove small amounts of ethylene chlorobromide.

USES

The unique combination of nonflammability, chemical activity, bactericidal properties, and high specific gravity gives bromine and its compounds diversified uses. Bromine is important in the gasoline, pharmaceutical, sanitation, photographic, and textile chemical industries. It is used for agriculture purposes and in the production of fire-extinguisher, gauge, and hydraulic fluids. Mineral separation, permanent wave preparations, and the synthesis of dyes also employ the use of bromine.

Brominated organic compounds are the largest consumers of bromine. Ethylene dibromide, the chief compound of bromine, is used as a scavenging agent in leaded gasoline antiknock fluid to prevent the deposition of lead in engines. Other uses of ethylene dibromide are as a reagent in the synthesis of dyes and pharmaceutical intermediates, as a sedative, anaesthetic and antispasmodic agent, and as a solvent for gums and waxes. It is increasingly used in fumigation preparations for control of insects and pests in soil and seeds. Methyl bromide, 1,2-dibromo-3-chloropropane, and 1,3-dibromopropane are utilized in the production of fumigants. Ethyl bromide is used as an intermediate in organic synthesis and in the manufacture of dyes, perfumes, and pharmaceuticals, especially barbiturates. Bromotrichloromethane forms noncatalytic additions with olefins to yield flame-resistant polymers. Tetrabromoethane and bromotrifluoroethylene polymer are utilized as dense media in processing ores or separating solid materials. Trimelylene chlorobromide is used as an intermediate for tranquilizer drugs.

Elemental bromine is used as a bleaching and disinfecting agent, as an alytical reagent in the laboratory, as a swimming pool sanitizer, and for synthesis of bromine compounds. It is used in the manufacture of dyes, ink, resins, and leather and rubber products. The military has used bromine in poison and tear gases.

Chlorobromomethane is used as a noncorrosive fire-extinguishing fluid in homes, factories, and warehouses and as a solvent in organic synthesis. Dibromodifluoromethane is utilized as fire extinguisher at missile bases. Tris (2,3-dibromopropyl) phosphate, tetrabromo phthalic anhydride, and tetrabromo bisphenol-A are used as fire retardants in the manufacture of plastics. Tris (1-bromo,3-chlorisopropyl) phosphate is used as a flame retardant in urethane foam and for certain synthetic fibers. Monobromotrifluoromethane is utilized as an extinguishing agent for fuel and electrical fires.

Metal compounds of bromine are used for the production of high-purity metals. Potassium, sodium, and ammonium bromides are used as nerve sedatives in medicinal preparations and for the preparation of silver bromide emulsions used on photographic films, plates, and papers. Ammonium bromide has minor use in process engraving and lithography. Calcium bromide is an excellent dehydrating agent. It serves also as a sedative in pharmaceutical preparations, as an intermediate in the preparation of organic calcium compounds, and in photography.

Lithium bromide is used in air conditioners. Potassium bromate is used in bread to improve the texture and reduce carbohydrate loss and as a neutralizer in permanent wave preparations. Zinc bromide solutions serve as windows in atomic laboratories to hold back gamma radia-

tion. Zinc bromide is used also as an absorbent in humidity control, as a component of nonflammable nitrocellulose compounds, in rayon finishing, and as a catalyst.

Hydrobromic acid is used as an intermediate in other chemical processes.

BYPRODUCTS AND COPRODUCT RELATIONSHIPS

At Searles Lake bromine is recovered as a coproduct from brine that also yields soda ash, salt cake, potash, borax, and lithium minerals. Bromine produced in Texas and California from sea water, and in Michigan from brine, is a coproduct of other compounds. Bromine is produced in conjunction with oil production at El Dorado, Ark. In Israel, bromine is extracted from waste liquors of a potash plant. Bromine is extracted as a coproduct of potash production in Germany.

ALTERNATE MATERIALS

The chemical properties of chlorine and iodine are similar to those of bromine, and these materials are sometimes substituted for bromine. Some substitutes for ethylene dibromide-tetraethyl lead antiknock fluid have been introduced, but the use of ethylene dibromide has continued to grow.

The production of very high-octane gasoline by catalytic cracking and reforming methods is costly. A method of raising the octane rating of low-grade gasoline to the level required by today's engines is to add antiknock fluid. Thus, gasoline containing tetraethyl lead and ethylene dibromide antiknock fluid can be substituted for high-octane nonleaded gasoline.

RESERVES

Known quantities of recoverable concentrations of bromine in sea water and brines are sufficient to supply the U.S. requirements indefinitely. In addition to the present commercial extraction process from sea water, a potential yield of 300,000 pounds per year could be realized from a desalination plant producing 1 million gallons per day of fresh water (*11*).

Indicated reserves and potential resources of bromine in brines obtained from saline deposits which underlie large areas of Michigan and from oil-well brines in Arkansas are large; however, no definite assessment has been made of the quantity.

Sea water, brines from closed basins, oil-well brines, and saline deposits furnish all continents with large indicated reserves and potential resources of bromine. The richest known source outside of the United States is the Dead Sea which contains about 56 percent bromine.

SOURCES OF STATISTICAL INFORMATION

The Bureau conducts an annual canvass of primary domestic producers and publishes figures on production of bromine and bromine compounds as measured by sales. Figures on exports and imports of bromine are compiled and published by the Bureau from data supplied by the Bureau of Census. Figures on production of bromine and bromine compounds in various foreign countries are obtained from State Department Dispatches and published in Mineral Trade Notes. An annual summary of prices for bromine and its compounds is compiled and published from data in the Oil, Paint and Drug Reporter.

PRODUCTION, CONSUMPTION, AND TRADE

About 75 percent of the bromine produced in the United States is converted to ethylene dibromide and consumed chiefly in the nation's automobiles. More than 5 percent is utilized in the production of fumigants.

The tariff schedule of the United States imposes the following duties on imports from non-Communist countries: Bromine 10 cents per pound, potassium bromide 4 cents per pound, sodium bromide 10 cents per pound, ethylene dibromide 2.4 cents per pound plus 12 percent ad valorem.

International trade is a relatively minor factor in the bromine industry. In 1963 the United States exported 11 million pounds of bromine and its compounds, valued at $2 million. Imports of special compounds totaled 374,012 pounds valued at $167,615.

STRATEGIC CONSIDERATIONS

Bromine is not on the list of strategic and critical materials. Concentration of the producing industry in two main areas presents a potential emergency supply problem, as bromine and its compounds have a number of important military uses such as in firefighting fluid and poison gases.

PRICES AND COSTS

The price of elemental bromine in 1963 ranged from 21.5 to 33 cents per pound. Purified bromine in cases, carlots, delivered east of the Rocky Mountains, sold for 32 cents per pound and in tanks, carlots, same basis, sold for 21.5 cents per pound.

TABLE 1.—*Bromine and bromine compounds*[1] *sold by primary producers in the United States*

[Thousand pounds and thousand dollars]

	1954–58 (average)	1959	1960	1961	1962	1963
Elemental bromine:						
Gross weight	9,921	12,537	18,878	17,706	23,106	26,248
Bromine content	9,921	12,537	18,878	17,706	23,106	26,248
Value	$2,364	$2,785	$3,892	$3,510	$4,267	$4,443
Bromine compounds:						
Gross weight	210,584	218,901	188,070	194,791	200,866	212,335
Bromine content	177,471	182,946	156,132	163,092	167,641	177,085
Value	$42,302	$48,723	$40,745	$41,007	$42,350	$44,115
Total:						
Gross weight	220,505	231,438	206,948	212,497	223,972	238,583
Bromine content	187,392	195,483	175,010	180,798	190,747	203,333
Value	$44,666	$51,508	$44,637	$44,517	$46,617	$48,558

[1] Bromine content calculated as theoretical bromine content present in compound.

The prices of bromine compounds were quoted as follows: Potassium bromide, 39 to 40 cents per pound; potassium bromate, 49 cents per pound; sodium bromide, 40 cents per pound; ammonium bromide, 44 cents per pound; ethylene dibromide, 30.5 cents per pound; methyl bromide, 62 to 79 cents per pound.

TAXES

Bromine producers (domestic and foreign) are granted a 5-percent depletion allowance under the Federal Income Tax Law. There are no special taxes levied on the bromine industry.

TRANSPORTATION

Bromine is a corrosive liquid and highly toxic. It requires special handling and transportation under paragraph 73–252 of the Interstate Commerce Commission regulations. A white label is necessary for shipments under paragraph 73–407 of the same regulations. Small quantities are shipped in cases of nine 6.5-pound glass bottles with lead caps packed in expanded mica, diatomaceous earth, or other inert absorbents. Larger quantities are shipped in 10-gallon lead-lined steel drums or in special nickel-clad or lead-lined cars (1). Requirements for tank car shipments are listed in paragraph 73–252, section A3 of the regulations.

RESEARCH

Most research by producers is directed toward the development of new markets and the improvement of product quality. Recently, research has been concentrated on organic bromides. The Bureau is conducting research on the use of bromine heavy liquids for the separation of minerals. Ethylene dibromide and tetraethyl lead, used in automobile motors as antiknock fluid, forms volatile lead halides and complex compounds containing lead halides, which are carried by the exhaust into the atmosphere. The specific reactions that occur in the presence of sunlight to produce eye irritation and oxidant substances known as smog and the role of bromine compounds in the formation of smog are not clearly understood. Air-pollution studies involving gasoline-motor exhaust are being conducted by the Bureau at Bartlesville, Okla. Commercial laboratories and companies also are studying these problems.

OUTLOOK

A growth rate of 4 percent is expected in the bromine market for the short-term outlook. This rate is comparable to the anticipated growth rate of 3.9 for personal consumption expenditure-durable such as automobiles and slightly higher than the anticipated growth rate of 3.5 for tetraethyl and tetramethyl leads. Moderate growth is expected in the consumption of elemental bromine, high-purity bromine, methyl bromide, bromochloromethyl hydantion, tris (2,3-dibromoprophy) phosphate, tetrabromo phthalic anhydride, tetrabromo bisphenol-A 1,3-dibromopropane, and hydrobromic acid.

The trend for each major producer to concentrate research, development, and market expansion effort on its own particular bromine products, is expected to continue.

The long-term outlook for the consumption of bromine is not clear; much depends upon the research of the major producers. Use of the turbine automobile engine would contract the dibromide market, and competition from iodine as a sanitization agent for swimming pools could affect the elemental bromine market. However, increased use of brominated compounds as fire-retardant plastics, additional applications of bromine compounds as intermediates in industrial processes, and improved techniques in producing high-purity metals by sublimation of metal bromides will facilitate growth in the industry.

PROBLEMS

The uncertain market for ethylene dibromide as a gasoline additive and a lack of market diversification will necessitate continued research by the industry. Moreover, commercial applications of laboratory data and methods must be adopted.

Development of safer forms and procedures are required before approval by government agencies and public acceptance will be obtained for the use of bromine as a sanitization agent for home swimming pools.

The high cost of bromine relative to the cost of chlorine deters its wider use and increased consumption.

CADMIUM

By Harold J. Schroeder[1]

CADMIUM is a soft, malleable, silver-white and relatively rare metal. For many years after its discovery in 1817, cadmium had few applications. In 1910 production was about 100,000 pounds, chiefly in Germany. U.S. production began in 1907, and in 1917, 1919 and ensuing years this country was the leading producer. Demand accelerated after 1919, and in 1963 20 countries produced a total of approximately 26 million pounds of cadmium.

Cadmium is largely associated with the extensively mined zinc sulfide mineral, sphalerite. Accordingly, production of cadmium is almost entirely a byproduct from processing zinc-bearing ores, and the producers of cadmium are the principal producers of zinc or zinc pigments. During 1963 in the United States 10 firms produced cadmium from primary sources and 2 other sources.

The United States has dominated world production since 1919, reaching 81 percent of the total in 1947 but thereafter trending downward to 40 percent for 1961–63. A record domestic output of 11.1 million pounds of cadmium was attained in 1962; the 1959–63 average was 10.1 million pounds, representing a recovery of 11.4 pounds of cadmium per ton of slab zinc produced. For the 1959–63 period about 14 percent of the cadmium was derived from imported cadmium flue dust, and the balance principally from domestic and imported zinc concentrates.

The United States is the largest consumer of cadmium, averaging about 11.3 million pounds per year for 1961–63. Foreign trade in cadmium was relatively small prior to 1952 and since then has been quite variable with most years showing a net import figure.

The first substantial use for cadmium was in paint pigments, but after 1919 its leading use was in plating. In 1963 the major uses were in plating, 55 to 60 percent; pigments and compounds, 30 to 35 percent; and alloys, 7 to 10 percent. Compounds have found increasing applications in plastics, nickel-cadmium batteries, and television tubes. Cadmium used in alloying is principally for solders, brazing alloys, and low-melting-point alloys. Small but important applications of cadmium have been developed for uses such as nuclear reactor control rods, radiation detection devices, photoconductive elements, and transistors.

The quoted price of cadmium metal has ranged from $0.90 per pound in 1945, to $2.55 in 1951, $1.36 in 1959, and $3.00 from yearend 1963 through 1964.

Cadmium will probably be used to the extent of its availability and domestic consumption is expected to increase from about 11 million pounds in 1964 to 12 million pounds by 1970. The higher prices established in 1963 should shift the consumption pattern from plating and pigments towards compounds used in plastics, batteries, and television tubes.

BACKGROUND (18, 19)[2]

Cadmium was discovered in 1817 by a German professor of metallurgy, F. Strohmeyer, while investigating impurities in zinc carbonate from the zinc works at Salzgitter. Strohmeyer and other investigators soon discovered that the new element was a minor constituent of most zinc ores and became concentrated in the flue dusts of zinc distillation furnaces. Small quantities of cadmium in the sulfide form were used in paint pigments, but for more than 60 years after its discovery few additional applications were found. In the latter part of the 19th century new uses in plating steel, in low-melting alloys, and in chemical reagents were developed. However, consump-

[1] Commodity specialist.
[2] Italicized numbers in parentheses refer to items in the list of references at the end of this chapter.

tion of cadmium did not achieve substantial growth until after 1919, following the work of M. J. Udy on a new cadmium-electroplating process. Improved recovery methods were devised and until recent years productive capacity has generally been in excess of demand for cadmium.

SIZE, ORGANIZATION, AND GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

Cadmium is recovered almost entirely as a byproduct during roasting, smelting, or other processing of zinc bearing ores. Accordingly, many producers of zinc or zinc pigments produce primary cadmium as an integral part of their operation and in some cases also by treating residues and flue dusts collected by other zinc producers.

World production reached around 100,000 pounds by 1910 with Germany accounting for about 90 percent of the total. U.S. production began in 1907 with 14,000 pounds produced by the Grasselli Chemical Co., and in 1910 American Smelting & Refining Co. began production at its Globe, Colo., plant. Other firms entered the field and the United States was the leading producer in 1917 when output reached 207,000 pounds. In 1918 the top ranking position reverted to Germany but since 1919 the United States has been the leading cadmium producer and in 1962 achieved a record 11.1 million pounds, 41 percent of the world total. Domestic cadmium metal production from 1907 to 1963 totaled nearly 250 million pounds.

Twenty countries produced cadmium in 1963 with a total output of about 26.3 million pounds. The United States, the U.S.S.R., Canada, Japan, and Belgium, in ranked order, accounted for 81 percent of the total. The geographical source of the ores yielding recoverable cadmium is not recorded, but it is roughly proportional to the mine output of zinc. All of the cadmium produced in Belgium and part produced in the United States and Japan are from imported ores, while Canada exports additional quantities of cadmium contained in zinc concentrate.

Domestic producers of primary metallic cadmium and their plant locations follow: American Smelting & Refining Co. (Corpus Christi, Tex., and Denver, Colo.); American Zinc Co. of Illinois (East St. Louis, Ill.); The Anaconda Co. (Great Falls, Mont.); Blackwell Zinc Co. (Blackwell, Okla.); The Bunker Hill Co. (Kellogg, Idaho); The Eagle-Picher Co. (Galena, Kans.); National Zinc Co., Inc. (Bartlesville, Okla.); The New Jersey Zinc Co. (Dupue, Ill., and Palmerton, Pa.); St. Joseph Lead Co. (Josephtown, Pa.); and Sherwin-Williams Co. (Coffeyville, Kans.). Domestic producers of secondary metallic cadmium are Arkansas Metals Co. (Jonesboro, Ark.) and United Refining & Smelting Co. (Chicago, Ill.).

There are many consumers of cadmium in the United States. A consumer survey by the Bureau of Mines in 1960 gave the following data: (1) Of the 1,526 respondents, representing 74 percent of apparent commercial consumption, approximately 1,400 gave plating as the sole or major use; (2) 809 plants consumed 1,000 pounds or more and accounting for 96 percent of the reported total; and (3) 51 plants consumed in excess of 25,000 pounds and accounted for 46 percent of the total. Of these 51 plants 35 were engaged in plating and represented 25 percent of the reported consumption for plating. Eight plants consumed 86 percent of the cadmium used in alloys, and seven plants consumed 95 percent of that used for pigments and chemicals.

Approximately 58 percent of the cadmium-consuming industry of the United States is in States bordering the Great Lakes. Of these States, Illinois accounts for about 13 percent, New York 11 percent, Ohio 10 percent, Michigan 8 percent, Pennsylvania 8 percent, Indiana 4 percent, Wisconsin 3 percent, and Minnesota 1 percent. New England contains about 14 percent of the consuming industry with Massachusetts accounting for 7 percent and Connecticut for 6 percent. The remaining 28 percent of the consuming industry is distributed among the other States.

The large consumers of cadmium normally receive their supplies directly from the producer or from direct delivery of imports arranged by a metal dealer. The small consumers of cadmium, chiefly the platers, are generally supplied by an intermediate distributor.

DEFINITION OF TERMS, GRADES, AND SPECIFICATIONS

Cadmium is a soft, malleable, silver-white metal when freshly cut. On exposure to moist air the luster dulls owing to formation of a thin coat of cadmium oxide. Some of the physical constants of cadmium are (*18*) atomic number, 48; atomic weight, 112.41; density, 8.65 grams per cm^3 at 20° C; melting point, 321° C; and boiling point, 767° C. Cadmium combines readily with many metals and forms an adherent coating on ferrous metals, properties important in its widespread use. Chemically, cadmium is almost always divalent. It reacts with solutions of the halogens to form corresponding halides, is dissolved in most inorganic and some organic acids, and is not soluble in alkalis. The corrosion resistance of cadmium in rural and

marine atmospheres is good but in industrial atmospheres, particularly where sulfurous fumes are present, corrosion is rapid (*20*). Fumes of cadmium and its compounds and solutions of the compounds are quite toxic (*15*).

Cadmium is produced in several forms. Platers prefer cast ball shapes, some chemical and pigment users prefer sticks or flakes, and certain alloyers desire slabs, ingots, or other shapes. Cadmium sponge is consumed by some compound producers, and several of the cadmium metal producers convert the molten metal directly into the oxide.

American Society for Testing and Materials specifications have not been established for cadmium, but in 1962 the society appointed a task group to develop such specifications and substantial work has been done towards that end. Most cadmium produced in recent years has been at least 99.95 percent pure. Allowable limits of specific impurities depend upon the intended use. Platers permit up to 0.05 percent lead and 0.033 percent zinc, while for most other uses maximums allowed are 0.025 percent lead and 0.02 percent zinc. Cadmium used for pigments must be low in thallium, and solder makers cannot use cadmium with even trace amounts of aluminum.

When shipped to consumers, cadmium sponge has a moisture content of about 25 percent packaged in bags and 35 percent packaged in drums. Even with this precaution substantial oxidation occurs and the cadmium contents on a dry analysis basis are typically 86 percent and 92 percent respectively.

Cadmium of 99.999 percent purity or higher is sold, particularly for electronic uses.

TECHNOLOGY

Cadmium is a relatively rare element, with the abundance in the earth's crust estimated at 0.5 gram per ton. Fortunately for recovery purposes much of this is associated with the extensively mined zinc sulfide mineral, sphalerite, and zinc concentrates from sulfide ore deposits contain from trace quantities up to 1.4 percent cadmium. Cadmium occurs with sphalerite as a solid solution, or as a yellow sulfide coating which is the mineral greenockite if in crystalline form and the mineral xanthochroite if amorphous. Upon weathering, the cadmium sulfide is altered to the oxide or to the carbonate (otavite).

Recovery of the cadmium during processing of zinc-bearing ores follows a variety of procedures (*3–4, 12, 14*). Each system is largely based on the fact that the melting and boiling points of cadmium and its compounds are lower than those of zinc and its analogous compounds, and on the easier reduction of cadmium oxide.

During the roasting and sintering of zinc concentrate, cadmium is concentrated in the collected fumes and baghouse dusts. In lead and copper smelters the initial cadmium content of the feed is low and the fumes must be recycled before the concentration reaches bleed-off levels. Cadmium content of fumes can be upgraded by refuming under controlled conditions in a kiln or reverberatory furnace. In the electrolytic method of producing zinc, the roasted concentrate and the collected fumes are taken into solution with sulfuric acid and a copper-cadmium sludge is precipitated by adding zinc dust. The fumes or sludges may contain from 5 to 50 percent cadmium.

One method of recovering the cadmium is to dissolve the fume or sludge in sulfuric acid, remove impurities by chemical means, precipitate a zinc-cadmium sponge by fractional cementation with zinc dust, redissolve the oxidized sponge in sulfuric acid, and selectively electrodeposit a high-grade cadmium on aluminum cathodes. As an alternative, a controlled addition of zinc dust to the cadmium-containing solution results in an incomplete precipitation of nearly pure cadmium sponge which is briquetted and charged to a retort for upgrading by distillation, then remelted and cast into shapes. In either case the spent liquor is recycled through the zinc recovery process to recover the remaining metal values.

A variation of the foregoing procedures is to take the cadmium into solution by treating a water slurry of the fumes or residue with chlorine gas. After filtering and acidifying, the cadmium is recovered from the solution using the zinc dust precipitation and subsequent steps described previously.

Another method is to combine the fume containing cadmium with the roasted zinc concentrate and allow the cadmium to remain with the zinc produced by distillation methods. In refining the zinc by fractional distillation a cadmium-rich fume is collected and is purified by one of the described methods and cast into shapes.

USES

The largest use of cadmium is for plating manufactured items of steel and other materials used in electrical equipment, transportation, hardware fasteners, and various other items. Ease of plating, even deposition, and excellent corrosion resistance in normal atmospheres, marine conditions, and alkalies give cadmium a wide acceptance for this purpose. Most plating is by electro-deposition (*21*) although parts to be subjected to high stresses may be plated by vacuum vapor deposition to reduce hydrogen embrittlement (*13*).

Cadmium sulfide, sulfoselenide, and lithopone are extensively employed for pigments in a color range of yellow, orange, and red. The pigments exhibit exceptional color permanency even under extreme industrial atmospheres. Other cadmium compounds are finding increased applications, such as stearate for vinyl plastics, nitrate for nickel-cadmium batteries, and phosphors for television tubes (7).

Cadmium combines readily with other metals. A series of solders and brazing alloys contain cadmium as an important constituent along with varying quantities of copper, lead, tin, zinc, or silver. Cadmium is alloyed with lead, tin, and bismuth to form a series of low-melting-point alloys. Small amounts of cadmium are sometimes added to copper to improve strength and hardness with little loss in electrical properties. Cadmium-base bearing metals, extensively used during World War II, are now seldom used. Nuclear reactor control rods and containers for uranium alloys have been made from cadmium alloys.

Both nickel-cadmium and silver-cadmium storage batteries have a high energy to weight ratio and rapid discharge and recharge rates, and both function well in low-temperature operation. They have gained popularity in airplanes, earth satellites, missiles, and small portable items such as shavers, flashlights, and tools.

Another small but important application is the use of cadmium sulfide crystals in photovoltaic cells, radiation detection devices, and photosensitive elements.

ALTERNATE MATERIALS

Zinc and chromium-nickel can substitute for cadmium as a plating material to protect iron and steel from corrosion. Tin and bismuth can be used in place of cadmium in low-melting alloys, and many alternate materials are competitive with cadmium for solders and brazing alloys. A similar competitive situation exists in the field of battery and electronic applications. The chromates of lead, zinc, and barium can in some instances replace cadmium yellow as a pigment. Atomic energy cadmium control rods, which limit neutron activity in an atomic pile, can be replaced by boron, hafnium, samarium, europium, and gadolinium.

Despite vulnerability to substitution in virtually every application, there are enough uses for which cadmium has the desired properties, availability, and price to maintain the demand.

RESERVES

Since cadmium production is almost entirely a byproduct of processing zinc-bearing ores, cadmium reserves are a function of zinc reserves. Analysis of selected samples of zinc concentrates shows a range of 0.5 to 0.6 percent in concentrates from Mexico, 0.1 to 0.4 from Canada, 0.17 to 1.38 from Peru, 0.14 to 0.20 from Australia, and 0.15 to 1.29 from the United States. Owing to the wide range of cadmium contents and incompleteness of data for most ore sources, reserves can only be approximated. Based upon calculated zinc reserves and assigned cadmium contents, the world reserve of cadmium in ore is estimated at 900 million pounds. North America is estimated to possess about 43 percent of this total, principally in Canada and the United States. Eastern and Western Europe are estimated to have 30 percent of the total, and Australia, Africa, Asia, and South America have the remaining 27 percent.

Processing the assigned world cadmium reserves by present technologies would recover about 500 million pounds of cadmium, a 20-year supply at the current rate of consumption.

A minor cadmium resource exists in cadmium-bearing scrap materials such as old batteries, low-melting-point alloys, and process residues.

SOURCES OF STATISTICAL INFORMATION

The Bureau of Mines collects data quarterly on production of metal and compounds and on metal stocks at metal producers, compound manufacturers, and metal dealers. Cadmium consumption surveys were conducted in 1955, 1956, and 1960. The Bureau of the Census, U.S. Department of Commerce, disseminates domestic import and export statistics monthly. The American Bureau of Metal Statistics publishes annual production data for U.S. and Canadian companies that release this data.

The British Bureau of Non-Ferrous Metal Statistics publishes production and consumption data for the United Kingdom, Canada, Australia, Italy, Belgium-Luxembourg, and Norway. Minerais et Metaux (Paris) gives similar data for France.

PRODUCTION, CONSUMPTION, AND TRADE

The United States became the leading producer of cadmium in 1917 with an output of 207,000 pounds. By 1925 this quantity had more than doubled, and by 1931 it was more than 10 times greater. By 1939 output was 4.4 million pounds; the average for 1941–45 was 7.8 million pounds. Annual output for 1959–63 averaged 10.1 million pounds, with a record 11.1

million pounds in 1962. The increased cadmium output has resulted largely from increased zinc output and improved recovery of cadmium. In 1939 slab zinc output was 557,000 tons with 7.9 pounds of cadmium recovered per ton of zinc; the average figures for 1959–63 were 904,000 tons and 11.4 pounds.

Production of cadmium in the remainder of the world has increased rapidly so that the U.S. proportion of the total has trended downward from 81 percent in 1947 to 53 percent by 1958 and 40 percent for 1961–63.

In the United States the metal output in 1963 derived from imported cadmium flue dust was approximately 11 percent, compared with an average of about 15 percent for the preceding 5 years. Except for a relatively small quantity recovered from scrap, the balance of metal output was obtained from processing domestic and imported zinc and other base metal concentrates with the foreign source estimated to be the largest item. The main sources of imported zinc concentrates were Mexico, Canada, and Peru.

Apparent consumption, computed from production, net foreign trade, and industry and Government stock changes, averaged about 6.5 million pounds per year between 1945 and 1952 and thereafter trended upward to an average of 11.3 million pounds for 1961–63. A 1960 consumption survey, accounting for 74 percent of apparent consumption, recorded that about 70 percent of the cadmium was used for plating, 21 percent for pigments and other compounds, and 8 percent for alloys including solder. Estimates for 1963 are plating, 55 to 60 percent; pigments and compounds, 30 to 35 percent; and alloys, 7 to 10 percent. The decline for plating is attributed to difficulties platers have had in obtaining adequate supplies and to substitution of competitive materials as the price of cadmium increased. Most of the increase in pigments and compounds is attributed to use of cadmium in production of cadmium stearate, nitrate, and phosphors.

Foreign trade in cadmium was relatively small prior to 1952 and since then has been quite variable, with most years showing a net import figure. In 1956 imports were 3.1 million tons and in 1960 exports were 2.5 million tons; both values are about twice as high as has been recorded for any other year.

The import duty on cadmium metal, as established at the 1947 Geneva Trade Conference is $0.0375 per pound. Cadmium contained in flue dust, ores, and concentrates is duty free.

TABLE 1.—*World production of cadmium metal, by countries*

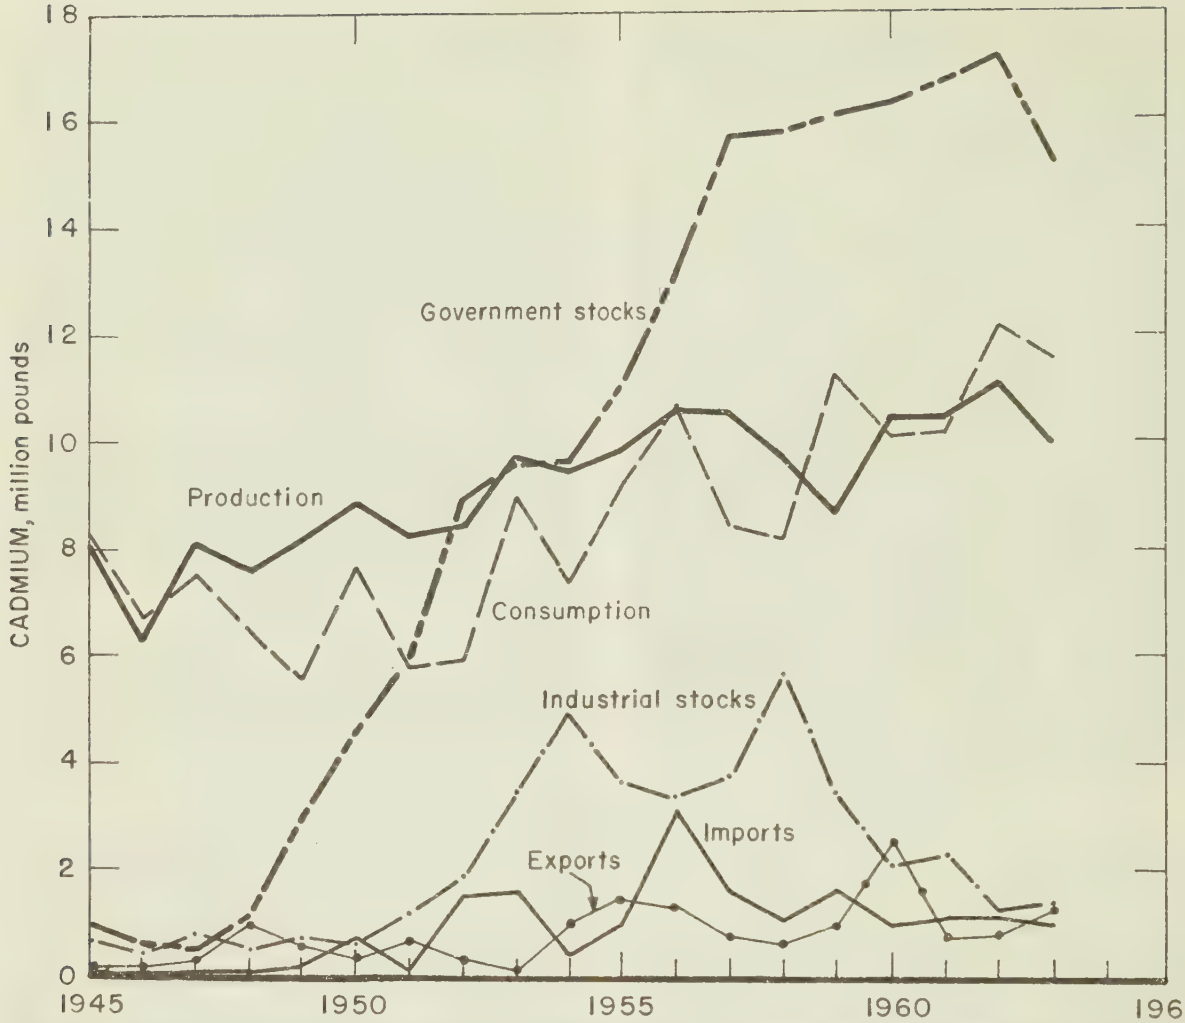

FIGURE 1.—Trends in Production, Commercial Consumption, Yearend Stocks, Imports, and Exports of Cadmium Metal in the United States.

STRATEGIC CONSIDERATIONS

Domestic cadmium metal production formerly exceeded commercial demand, but since 1959 it has fallen short. The source of over half of the recovered cadmium is estimated to be imported cadmium flue dust and zinc concentrates, the bulk coming from Mexico, Canada, and Peru. Canada and Peru also produce substantial quantities of cadmium metal.

Purchase of cadmium under the Strategic Stockpile Act (1946) began in 1948, and buying for the minimum stockpile requirements was completed in 1955. Cadmium was acquired for a supplemental stockpile from 1956 through 1963 under provisions of the Agriculture Trade Development and Assistance Act (1954).

Total inventory of Government stocks increased from 1 million pounds in 1948 to almost 9 million pounds in 1952 and from 9.6 to 15.7 million pounds from 1954 to 1957. At the end of 1962 stocks were 17.2 million pounds, 10.7 million in excess of the 6.5 million pounds announced in March 1962 to be needed for defense. In accord with Public Law 88–8, sales amounting to 2.0 million pounds were made in 1963 from the Government stockpile, reducing the total to 15.2 million pounds on June 30, 1964. Of the total, 7.7 million pounds was in the national (strategic) stockpile, and 7.5 million pounds in the supplemental stockpile. Public Law 88–319, signed by the President on June 12, 1964, authorized disposal of 5.0 million pounds of cadmium, and sales began on July 1, 1964.

PRICES

Cadmium prices have changed substantially since World War II. Quoted producer prices for bars, sticks, and other shapes in lots of 1 to 5 tons, which averaged $0.90 per pound in 1945, advanced for 6 successive years to $2.55 in 1951. Prices declined during the next 8 years to $1.36 for 1959. Thereafter another upward trend occurred and the average for 1963 was $2.26. The price advance during 1963 was from $1.70 to $1.80 at the start of the year to $3.00 at yearend. The $3.00 price was maintained throughout 1964.

RESEARCH

Research relating to discovery, mining, and milling of cadmium is an incidental part of research on zinc or zinc-containing ores. Likewise, much of the research dealing with production of cadmium metal is associated with the larger problems of recovery of the parent base metals. Recovery of cadmium from certain residues, fumes, and other smelter products has been investigated by metal producers (*11*, *24*) and the Bureau of Mines (*5*, *16*, *22*). In recent years research on production has emphasized methods of obtaining high-purity cadmium metal and compounds required for many of the newer uses (*9*, *17*).

The bulk of research on cadmium has been for purposes of utilization. Although plating is one of the oldest uses, a significant amount of research has recently been conducted, particularly with regard to reducing hydrogen embrittlement in plated steel parts subjected to high stress (*2*). Among the methods employed were use of special high-purity plating solutions, heat treatment of the steel part both before and after plating, and use of a vacuum deposition plating procedure. Much research continues on pigments, including development of several cadmium-mercury compounds with improved characteristics for tinting strength, light resistance, and alkali and acid resistance. Other research showed that cadmium compounded with alkyl and aryl phosphites, stearates, and laurates is effective in reducing surface tackiness and controlling age or heat degredation processes occuring in many vinyl resins (*6*).

Perhaps the greatest impetus to research on cadmium in recent years has been the applications of this metal and its compounds in the new fields of electronics, atomic energy, and space exploration (*2*, *8*, *10*, *23*). These investigations have both advanced knowledge of basic properties and explored specific applications. Included in this research are studies by many investigators on characteristics of cadmium compounds for use in transistors, photoconductors, and other functional components in electronic equipment, atomic energy-directed research to use cadmium in control rods for nuclear reactors and container vessels for atomic materials, space-directed research utilizing coated cadmium sulfide crystals for direct conversion of light into electricity, and improvements in nickel-cadmium and silver-cadmium storage batteries.

OUTLOOK

Consumption of cadmium in the United States should rise slowly to about 12 million pounds by 1970. Since in recent years demand has exceeded new supply, the forecast consumption is based on the projected probable availability of cadmium from domestic production, imports, and releases from the national stockpile.

New cadmium supply will continue to be obtained predominately as a byproduct from zinc ores and zinc-bearing lead and copper ores. Cadmium obtained from secondary sources will contribute a minor part of the supply. Hence, output will depend largely upon productivity of zinc smelters, estimated to grow worldwide about 3 percent per year. Domestic zinc smelting is anticipated to exhibit little growth, and imports of Mexican cadmium flue dust, representing a substantial quantity of source material for cadmium production, are forecast to decrease. Some small improvement in recovery of cadmium should offset the reduced quantity of cadmium obtained from flue dust, leaving output from domestic plants substantially at present levels.

Changes in the use pattern of cadmium will continue in adjustment to the large price advances of 1963. Plating will remain the largest single use, although in a few years it will probably decline to about one-half of total consumption. The higher price also promotes substitution of competitive materials for cadmium pigments, and use of cadmium for this purpose will decline from the estimated 15 percent consumed in 1963. Price does not appear to be as great a factor in use of cadmium in solders, low-melting point fusible alloys, and other alloys; consumption for these purposes should remain stable at 7 to 10 percent of total use.

Cadmium compounds, other than those used for colors, represent the most rapidly growing area of use. Consumption of cadmium for this

780-887 O—65——12

purpose is likely to increase substantially from the estimated 15 to 20 percent for 1963. The most important applications will be the stearate for vinyl plastics, the nitrate for nickel-cadmium batteries, and the phosphors for television tubes.

PROBLEMS

A continuing problem to the cadmium producer and consumer is that output depends on base-metal production and thus is virtually unresponsive to changes in demand. An example was the acute shortage of cadmium in 1963 despite knowledge of diminishing stocks and several price advances in the preceding 3 years.

There is a lack of comprehensive knowledge on the geographic source of ore for cadmium production, partly because few ores contain enough cadmium to receive a smelter credit for payment. Thus there are few recorded data on domestic mine production of cadmium or quantities contained in imported ore. With such a poor record of existing output, the estimated reserves and resources of cadmium also are unreliable. The basic facts of occurrence of cadmium in relation to mineral association and genesis of ore deposits are not well enough understood to determine probable concentrations in presently known occurrences or to indicate new sources.

Investigations are needed to delineate problems associated with recovery of cadmium and to develop improved processing methods for reducing the milling and smelting losses. These studies are difficult since the low content of cadmium in the ore requires numerous complex steps in collecting and processing flue dust and residues, making determination of a material balance an involved and costly procedure.

Development of economically sound recovery techniques is required to permit reclamation of the increasing quantities of cadmium now being used in batteries.

A lack of widely accepted specifications for cadmium poses a marketing problem for the producer. There is a general deficiency in the knowledge of limits of impurities that can be tolerated for the different applications of cadmium.

Inadequate statistics on cadmium consumption hinder assessment of trends in usage and projection of requirements.

The toxicity of cadmium fumes requires safeguards during both production and consumption of cadmium and some of its compounds. Cadmium producers also need to take special precautions to prevent poisoning by arsenic which is present in the flue dusts used for plant feed.

The poor corrosion resistance of cadmium to sulfur compounds in industrial atmospheres limits the useful application of cadmium-plated products.

CARBON

By John W. Cole [1]

CARBON, considered the indispensable element, possesses many physical and chemical properties that make it invaluable to industry. Industrial carbon in this chapter includes all elemental carbon used industrially in applications other than as fuels or reductants, except natural graphites and diamond which are covered in separate chapters.

Industrial carbon is produced by two principal processes from vegetable matter, coal, petroleum and other natural hydrocarbons. In one process the raw material is calcined to drive off volatile matter and leave a high-carbon residue, and in the other, the raw material is partially burned in special combustion chambers and the carbon collected as a deposit or as a precipitate from combustion gases. The industrial carbon produced is not always of sufficient quality for immediate use but may undergo further processing either to remove any remaining impurities or to impart the desirable physical properties required by the end use.

The principal source of raw material for industrial carbon is petroleum and related products. Petroleum coke, a byproduct of thermally cracking various oil stocks in a coking still to yield coke, coker gas oil, and lighter oils and gases, is the preferred material for most uses because of its high-carbon content, low cost, and availability. High-grade petroleum fuel oil, natural gas, and acetylene (to a lesser extent) are used for the production of carbon black. Raw materials such as coal, metallurgical coke, and vegetable or animal materials are used when petroleum coke cannot be processed to produce the desired properties in the end product or when it is more economical to use them.

The United States is self-sufficient in all raw materials for industrial carbon. It has about one-third of the estimated coal reserve of the world, one-ninth of the proved petroleum reserve, and about one-third of the proved natural gas reserve. Reserves of animal and vegetable material are large and renewable.

Carbon is used principally in the manufacture of electrodes, adsorptive materials, chemical compounds, rubber, and pigments. Consumption should keep pace with the growth of the national economy, but current extensive research may find new uses, thereby increasing consumption. Graphites with special properties, such as oriented and recrystallized types, are being developed for use in space-age applications. As more knowledge of them is obtained, their use is expected to grow.

Carbon is not considered a strategic or critical material, probably because the United States is self-sufficient with respect to carbon-containing raw materials. However, carbon is essential for industry to function not only in times of war but also in times of peace.

Problems of the carbon industry are more technologic than economic although new and expanded markets are being sought. The relationship of the raw materials to the properties of the manufactured product, the effective utilization of manufactured carbon and graphite, and the wide range of properties required for end uses are the concern of the carbon industry.

The basic properties of both raw materials and manufactured products need to be studied in detail. In addition, improvements or new processing and manufacturing techniques need to be developed.

BACKGROUND

From the discovery that fire could be tamed to provide comfort and necessities for man, the uses of elemental carbon have ranged from depicting the exploits of cave dwellers, drawn with the charred ends of sticks from the tribal hearth, to its use as an ablative coating on the nose cones of space ships. Forms of elemental carbon range from common charcoal to spun

[1] Commodity specialist.

yarns and woven fabrics with strength and flexibility approaching glass, corrosion and heat resistance superior to metals and ceramics, and electrical resistance that invites its use for heating requirements from the gentle warmth of bed coverings to the white heat of industrial furnaces.

The growth of the carbon industry in the United States, as in the rest of the world, has been tied closely to industrial development. Its great expansion in the United States was triggered in the latter part of the 19th century by the development of the carbon electrode in France. Subsequent research in the utilization of electricity as a source of low-cost power formed the basis for the vast, complex manufactured-carbon industry of today. Carbon aided in the development and growth of the electrical, electrothermic, and electrolytic industries, which in turn resulted in expanded research in carbon utilization with a consequent enormous increase in growth of the carbon industry.

SIZE, ORGANIZATION, AND GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

Raw materials used in the production of carbon are petroleum, petroleum coke, natural gas, coal tar pitch, coal, beehive and byproduct coke, gilsonite coke, lignite, peat, nutshells, pulpmill waste, wood, and bone. An analysis of some of the materials is found in table 1.

TABLE 1.—*Range of analyses of carbon materials*

Material	Fixed carbon, percent	Moisture, percent	Volatile matter, percent	Ash, percent	Specific gravity
Coal:					
Anthracite	65. 0–85. 0	2. 4–14. 0	1. 5– 8. 5	6. 0–18. 0	1. 5
Bituminous	49. 0–79. 0	1. 8–19. 0	14. 0–40. 0	2. 8–19. 0	1. 36
Coke:					
Beehive	80. 0–95. 0	. 5– 1. 5	. 3– 3. 0	4. 0–21. 0	1. 9
Byproduct	85. 0–95. 0	. 7– 3. 0	. 6– 3. 3	4. 0–12. 0	1. 9
Petroleum coke	82. 0–97. 0	. 4– 2. 0	4. 0–18. 0	. 5– 2. 0	1. 8
Pitch coke	90. 0–97. 0	. 5– 1. 5	1. 0–15. 0	. 3– 2. 0	1. 6–1. 9
Wood charcoal	84. 0–97. 0	1. 0–10. 0	1. 0–10. 0	1. 0– 4. 0	

During 1963, 34 petroluem refineries in 16 States produced 6.5 million tons of marketable petroleum coke. They are listed in table 2. Marketable petroleum coke, the residue from the distillation of oil, is produced and sold by refiners on long-term contracts to calcining companies or manufacturers of carbon products (*15*).[2] About one-half the petroleum coke sold for industrial use was calcined and used by companies producing primary aluminum. The other half was calcined by four companies at nine plants. Great Lakes Carbon Corp. calcined about three-fourths of the latter amount while the remainder was processed by Union Carbide Corp., Carbon Products Division; R. T. Collier Co.; and Speer Carbon Co., International Graphite & Electrode Division.

Most of the coke produced from coal mined in the United States is used for purposes other than industrial carbon. Approximately 10 percent of the 6,597,399 short tons of coke produced in 1963 by merchant oven- and beehive-coke plants was used for making industrial carbon products, chiefly in calcium-carbide production.

[2] Italicized numbers in parentheses refer to items in the list of references at the end of this chapter.

Wyoming	Texaco, Inc	Casper.

Substantial quantities of metallurgical coke suitable for the industrial carbon market were produced in 1963 from Utah gilsonite by the American Gilsonite Co., Gilsonite, Colo.

Raw or semiraw materials used for the production of charcoal and chars ranged from hardwood trees to pulpmill waste and animal bone. In 1960, the latest year for which statistics are available, 1,962 kilns owned by 297 operators produced 328,000 tons of charcoal. Of this amount 235,640 tons was briqueted, presumably for sale as fuel, and the remainder, 92,360 tons, was marketed in bulk. Most of the plants were in the Eastern United States near the principal consumers. Bone char is produced in byproduct plants for distribution to various consumers, principally sugar refiners. The number and location of these plants are unavailable.

Manufactured (artificial) graphite products were produced in 1963 by Union Carbide Corp., Carbon Products Division at Niagara Falls, N.Y., Clarksburg, W. Va., and Lawrenceburg, Tenn.; by Great Lakes Carbon Corp., at Niagara Falls, N.Y., Morgantown, N.C., and Antelope Valley, Calif.; by Speer Carbon Co., International Graphite & Electrode Division, St. Marys, Pa., and Niagara Falls, N.Y.; and by Stackpole Carbon Co., St. Marys, Pa. The Dow Chemical Co., Midland, Mich., produced graphite electrodes for its own use.

The carbon black industry in the United States, the principal world producer, has had a history of migration of the producing areas, steadily increasing demand marked by sudden sustained spurts as major new uses were developed, and abrupt changes in production methods.

Carbon black was undoubtedly produced sporadically in the United States during colonial times, but the first factory was erected at New Cumberland, W. Va., in 1872. The raw material was natural gas; when demand for gas as a fuel forced prices up, the carbon black producers migrated to areas where there was an excess of natural gas. About 1920, Louisiana became the major producing State, but by the end of a decade, Texas became, and remains, the chief producer.

Beginning in 1912, the use of carbon black as an additive to rubber vastly increased consumption; the rising demand, caused by this use, sharply accelerated during World Wars I and II. In 1963, the rubber industry used 94 percent of the carbon black consumed.

During World War II, a furnace process utilizing liquid hydrocarbons was developed that could produce most grades of carbon black. (Some furnace plants also use natural gas.) Up to that time, about 95 percent of the carbon black was produced from natural gas. By 1963, carbon black produced from liquid hydrocarbons amounted to 74 percent of the total U.S. production. Annual output of all kinds of carbon black was over 1 million short tons in 1963. Nine producers in 7 States operated 39 carbon black plants (table 1) with an annual capacity of about 1.2 million tons.

DEFINITION OF TERMS AND GRADES

Industrial carbon, for the purpose of limiting the scope of this chapter, is defined as any elemental carbon used industrially except that used for fuel and reductants and excluding natural graphite and industrial diamond. Carbons used by industry are usually in the form of finished products or materials that contain only minor amounts of impurities, but differ widely in physical characteristics. Terms such as baked, fabricated, amorphous, and manufac-

tured, have been used to qualify carbon in describing articles made by heating extruded or molded raw material to about 1,000° C. When the baking process is carried to higher temperatures (above 2,750° C), the carbon is converted to graphite and the finished product is called manufactured graphite, electrographite, artificial graphite, synthetic graphite, or simply graphite. Herein, it is called manufactured graphite to distinguish it from native or natural graphite.

Many terms used in the finished product segment of the industry are based on the application, such as electrode carbon, projector carbon, or brush carbon. *Green carbon* is coke that has been calcined, ground, mixed with a binder, and pressed into form preparatory to baking into a finished product.

Activated or *active carbon* is an amorphous material produced from coal, or animal and vegetable chars. To activate carbon, it is treated with superheated steam or acids to increase the surface area per unit weight which also increases its adsorption capability. *Bone black* or *bone char* is made by calcining degreased bones in the absence of air and is essentially carbon deposited on a skeleton of tricalcium phosphate.

Coke is a porous, amorphous form of carbon that is the residue of the distillation of volatiles from certain varieties of bituminous coal at high temperatures. The quality of product, that predominantly is used as a reductant for metals or as a metallurgical fuel, is often referred to as metallurgical coke. Coke is graded according to its chemical analysis, its compressive strength, and its resistance to impact and abrasion. The quality of coke is determined by its ash, volatile matter, fixed carbon, and sulfur content. Frequently the composition of the ash also is an important consideration in metallurgical coke.

Petroleum coke, in the form of delayed and fluid coke, is a product of coking processes used in refining petroleum and is the carbon residue left after the production of coker gas oil. *Fluid coke* is used primarily as a fuel. It is a sand-like material composed of small spheroidal particles. *Delayed coke* is the bulk type of petroleum coke discussed here that is used in the manufacture of industrial carbon. Almost pure carbon can be made by calcining petroleum coke above 850° C. Table 4 lists the generally used properties of petroleum coke to be used for anodes in the production of primary aluminum. Petroleum coke for use in the production of silicon carbides should contain neither more than 1 percent sulfur or ash nor less than 9 percent volatile matter. High iron and alumina in the ash are objectionable because they tend to form elemental graphite and silicon metal during the reaction. For use in the production of calcium carbide, petroleum coke should contain less than 2 percent ash, 0.1 percent phosphorus, 1 percent sulfur, and 13 percent volatile material.

TABLE 4.—*Generally used properties of petroleum coke suitable for manufacture of aluminum anodes*

	Green	Calcined
Volatiles, maximum percent	12.0	0.5

Real density, specific gravity		2.01–2.07

Graphite is an allotropic form of carbon that crystallizes in the hexagonal system. (See "Graphite" chapter.) Diamond also is a crystalline (isometric) allotrope of carbon. (See "Diamond" chapter.)

Pyrolytic graphite, *oriented graphite*, *and recrystallized bulk graphite* are terms used to designate high density, anisotropic, recrystallized manufactured graphite.

Carbon black is a term used to designate a group of nearly pure elementary carbons composed of spherical particles having diameters of 50 to 5,000 angstroms. Their production, physical characteristics, and uses are so different from other carbon materials that they merit special consideration. The pigment trade refers to carbon black from all sources simply as blacks. All carbon blacks, as produced, contain small quantities of hydrogen and oxygen and less than 1 percent ash. They are produced from natural gas, creosote oil, or petroleum fuel oil by partial combustion or thermal decomposition under carefully controlled conditions that determine their particle size, structure, and physical properties.

In the early days of the industry, carbon black was the designation for carbon derived from natural gas, and lampblack was carbon derived from petroleum fluids. Current practice is to designate all blacks as carbon black and to classify them primarily according to method of manufacure and, secondarily, quality. Table 5 shows the most important grades of carbon black in general use, although individual producers have many other brands, grades, and classifications. The two principal methods of manufacture are the channel method, in which small natural gas flames deposit black or soot on steel channels, and the furnace combus-

tion method, in which gaseous and liquid hydrocarbons are incompletely burned in closed retorts and furnaces and the carbon black collected from flue gases. *Channel blacks* are fine-grained, hard, and abrasion-resistant, while *furnace blacks* are soft and flocculent. Special blacks produced by thermal decomposition in preheated furnaces are termed *furnace thermal blacks*. *Acetylene black*, produced from acetylene gas, falls in this category.

TABLE 5.—*Grades of carbon black*

	Main base	Average particle diameter, millimicrons
Channel:		
HCC, high color	Natural gas	5–10
MCC, medium color	do	9–17
LCC, low color	do	17–25
MPC, medium processing (rubber)	do	25–30
EPC, easy processing (rubber)	do	30–33
Furnace (rubber):		
HAF, high abrasion	Oil	33–35
FEF, fast extruding	do	45
HMF, high modulus	Natural gas	55–65
SRF, semireinforcing	do	70–90
Thermal:		
FT, fine	do	150–200
MT, medium	do	250–500
Lampblack	Oil	70–200

Carbon blacks also are graded on the physical properties imparted to the substance to which they are added. About 94 percent of the carbon black produced goes into rubber as a reinforcing agent; the finer the particle size of the blacks the greater is their reinforcing ability. The manufacturing process can be controlled to produce various particle sizes to conform to the degree of reinforcing or abrasion resistance required. For inks and pigments, the degree of blackness is important. Other properties that are important include mass tone, tinting strength, surface area, oil adsorption, organic accelerator absorption, and pH. For certain uses, electrical resistance is an important property.

Technology (*1, 16*)

Carbon occurs in three allotropic forms: Amorphous with a density of 1.8 to 2.1; graphite with a density of 2.25; and diamond with a density of 3.51. Diamond crystallizes in the isometric system, hextetrahedral class, and graphite crystallizes in the dihexagonal-dipyramidal class of the hexagonal system. X-ray studies of amorphous carbon indicate that it also is crystalline although the crystals are too small to be seen with the unaided eye.

Carbon has an atomic number of 6, an atomic weight of 12.010, and six isotopes, C^{10} through C^{15}. Isotopes 12 and 13 are stable; the rest are radioactive with different half lives, the most important of which is C^{14} with a half life of about 5,360 years. The half lives of the other isotopes are a few seconds.

The element has four electrons in its outer shell which may be shared with those of other atoms to form an electron octet. Carbon atoms unite readily with each other or other elements in chains or rings. These compounds form the basis for the science of organic chemistry which lists well over half a million known compounds.

Carbon is inert chemically at room temperature, but oxidizes readily at elevated temperatures. It sublimes at about 3,600° C and boils at about 4,200° C. It is insoluble in all the usual solvents, but dissolves in many molten metals and either separates from them again on cooling or forms carbides with elements more electropositive than carbon.

A high thermal conductivity and a low coefficient of thermal expansion give carbon products a very high resistance to thermal shock. A unique quality among structural materials, carbon is 50 to 75 percent stronger at 4,500° F than at room temperature. It may be formed into shapes either by extruding, molding, or machining. It is a good conductor of electricity.

The geology, occurrence, extraction, and preparation of the mineral source materials, from which carbon is derived, are described in the "Coal," "Diamond," "Graphite," and "Petroleum and Natural Gas" chapters.

The raw materials used in producing industrial carbon, except for certain chars, must be high in fixed carbon and low in ash. The ash-forming constituents must be of the type that can be removed inexpensively. Desirable characteristics found in finished products are not necessarily inherent in the raw materials but may be the result of processing treatment. Most of the raw materials, including coke, are given a preliminary processing by calcination or charring which drives off volatile impurities and results in additional carbonization of hydrocarbons. For some materials, such as bone chars used as adsorbing agents, this initial processing results in a usable product requiring only crushing and sizing. Usually, however, secondary processing is necessary to produce the physical and chemical characteristics required by the particular end use. Processing may include beneficiation, forming, calcination, coking, charring, baking, chemical treatment, or a combination of two or more of these operations. Any or all stages of processing may be done at the raw material source, or by those who process the raw material in bulk form for customers, or by manufacturers of finished products.

Coal

Anthracite and bituminous coal contain ash-forming materials that either are inherent in the coal or extraneous material that is introduced during the mining cycle. To reduce ash-forming materials, the coal is washed, treated by float-sink methods, or upgraded by chemical means. The volatile materials are removed either by preliminary calcination or by baking in the finishing process.

Because bituminous coal is relatively high in volatile matter, its use is limited as a raw material in the production of carbon for many uses. Suitable types of bituminous coal are used to produce coke, which finds extensive use as metallurgical fuel, and to a lesser extent, as a raw material for carbon products.

Anthracite is principally fixed carbon, therefore it is low in volatile matter. Volatile constituents are removed by calcining at about 750° C in closed furnaces in the absence of air. Carbon companies purchase various sizes of anthracite, generally pea through buckwheat No. 4, to insure proper size distribution throughout the electrode or block.

Coke

Coal coke is made by distilling, or coking mixtures of bituminous coals in beehive or byproduct coke ovens.

The beehive oven is a primitive device that derives its name from its shape. It is filled with coal, part of which is allowed to burn with a limited supply of air. All the volatile matter, including gas, ammonia, and tar, escapes through an opening at the top of the oven, where it burns and is wasted.

Byproduct coke ovens are used for large-scale production of coke. Each oven is from 28 to 40 feet long, about 15 feet high, and 14 to 18 inches wide. Heat is supplied by burning gas outside the coking chamber walls. As many as 100 such ovens may be built contiguously in a solid battery. Coal is charged through several holes in the top of each retort, using a car traveling on tracks above the roof of the ovens. A charge consists of 12 to 20 tons of coal depending on the size of the oven.

Coke is produced after heating about 18 hours at about 980° C in the coke bed. Gases leave the chambers through collecting mains and pass successively through processes to recover tar, ammonia, and light oils before passing on to be used as fuel for heating the ovens. Excess gas is used in associated iron and steel plants or distributed through city pipelines to residential and commercial consumers. When coking is complete, the ends of the oven are opened and the red-hot mass of coke is pushed out of the oven by a ram. The ram is mounted on a structure (coke pushing machine) which travels on a set of rails and can be spotted to serve all the ovens in a bank or in several banks. The coke discharges into a special car driven by an electric motor and is transported to a tower where it is quenched with water.

Petroleum coke is produced in special coking units as a byproduct in the thermal cracking of heavy residual oils at 500° to 550° C (*20*). The primary purpose of the operation is to upgrade the residual oil into more valuable light products. The coke as produced contains hydrocarbons and about 95 percent carbon.

Petroleum coke is glossy gray or black, hard, and brittle. For many uses it should be low in sulfur and vanadium and, to facilitate calcining operations, low in chlorides and sulfates. As the final product of distillation processes, petroleum coke contains a concentration of the impurities existing often in trace quantities in the original petroleum. The physical properties of petroleum cokes vary, depending on the crude oil, processing cycles, coking procedure, and crushed particle size and shape.

Calcining companies collect the raw coke from the refineries in bulk form and process the material by firing in kilns for resale as calcined petroleum coke to manufacturers of carbon end products. Although high-purity is required for certain end uses (reactor-grade graphite for example) most calcining companies are not greatly concerned with sulfur and ash content in the raw coke because they can meet the calcined-coke specifications of consumers by blending.

Calcination is done in gas or oil-fired rotary kilns or retorts at about 1,300° C. The main purposes of this firing are to drive off any remaining volatile material and preshrink the coke so that volume changes in subsequent processing will be small and controllable. In addition, electrical and heat conductivities are increased. The calcined coke is then crushed and sized by screening to meet specifications of the consumer.

Charcoal and Chars (*1*)

Organic substances, such as wood and bone, are processed by partial combustion to form charcoal and chars. After carbonization, the material is crushed to size when it is ready for some uses or it may be given special treatment prior to application in other processes.

Both hardwoods and softwoods are used in the production of charcoal. Hardwoods yield hard granular material while the soft resinous woods yield a soft powdery charcoal. The

high-density species of trees yield the most charcoal. Wood carbonization is conducted in beehive kilns, ovens, and continuous retorts at end temperatures between 450° and 500° C. The carbonization time may run from a few days to several weeks.

In the kiln process, the woods are partially ignited under controlled air input conditions to allow only partial combustion. Charcoal yields are 800 to 900 pounds per cord (128 cubic feet) of the heavier woods and 600 to 700 pounds per cord of the lighter softwoods and hardwoods. Charcoal is the only product of kilns. Externally fired ovens and continuous retorts carbonize hardwoods and softwoods yielding charcoal, chemicals (pyroligneous acid), and waste gas. The byproduct carbonizers are equipped with wood predryers and charcoal coolers. The charcoal yield in oven and retort processes is 1,000 to 1,050 pounds per cord from hardwoods and 400 to 450 pounds from resinous woods.

The charcoal produced by these methods is crushed and sized and, depending on end application, is used as such or treated further to obtain physical and chemical characteristics desired in certain end uses. Occasionally, powdery charcoal is pelletized or agglomerated before use; for use in adsorption, it is activated to increase adsorptive characteristics. Activation is done by controlled oxidation with steam or carbon dioxide at 800° to 1,000° C, or with air at 300° to 600° C (*10*). Other activation processes involve heating with minerals and chemicals.

Chars are produced by the carbonization of bone, or dense materials like cocoanut shells or peach pits in horizontal retorts of the byproduct type. Bone is the predominant raw material. Fats, oils, and cartilaginous matter are extracted prior to processing. The bone is charred for 8 hours at about 800° C. The quantity of bone char produced is about 60 percent of the original preextracted charge. The resulting char contains about 75 percent calcium phosphate, 6 percent calcium carbonate, and 10 percent carbon. The carbon is dispersed as a fine film on the skeletonized phosphate and carbonate structure. After carbonization, the char is cooled in the absence of air, crushed, and screened.

Carbon Black

Carbon black is produced by two methods, channel and furnace. The furnace method is the more efficient. The number of channel plants has decreased from 15 in 1960 to 9 in 1963 while the number of furnace plants has increased from 27 to 30. In 1963, the yield of carbon black from natural gas was 4.63 pounds per thousand cubic feet of gas consumed. From hydrocarbon liquids the yield was 4.55 pounds per gallon of liquid feed.

The channel process uses natural gas which, in some cases, is slightly enriched with oil. The gas is burned from specially designed burner tips that produce smokey fan-shaped flames. The flames impinge on long steel channels which move slowly back and forth longitudinally. Carbon black is deposited as a sooty layer on the relatively cool channel, removed by stationary scrapers, and dropped into a hopper from which it is conveyed to storage for market preparation.

The channels and burners are housed in buildings called "burner" or "hot" houses, each containing from 2,000 to 3,500 burners. A carbon black plant may consist of hundreds of houses and hundreds of thousands of flames. Air is introduced at the top and bottom of the houses to control combustion. The different grades of carbon black are produced by changing the feed stock, air intake, burner design, and spacing. Draft, burner tip shape, atmospheric conditions, and kind of fuel are factors that affect quality and productivity.

In the furnace process carbon black is produced by burning hydrocarbon liquids and gases in a refractory-lined furnace at temperatures between 1,100° and 1,650° C. The carbon black produced is carried by hot combustion gases to water spray coolers where the gases are cooled by steps to about 200° C. The gas stream passes through cyclone separators, electric precipitators, and finally bag filters. The cyclones collect about 50 percent, the precipitators 40 percent, and the bag filters 10 percent of the carbon black entrained in the gas stream. The collected carbon black drops into hoppers from which it is conveyed to the packaging and and marketing area.

Acetylene black, one of the carbon blacks, is produced by the thermal decomposition of acetylene (C_2H_2). It was first produced by the channel method. It has been produced by explosive combustion based on the fact that acetylene under pressure of over 2 atmospheres will propagate decomposition through the entire volume if ignited by an electric spark. The most important method of commercial production is to heat acetylene to its decomposition temperature, 800° C. Since the reaction is exothermic, no additional heat is required after the reaction has started.

Acetylene black approaches the properties of finely divided graphite. It has a loose, spongy structure that almost defies compaction. When compressed, it will contract like other carbon

blacks but will soon reexpand when the pressure is released.

The technology of manufacturing graphite is described in the "Graphite" chapter.

Specialized Carbons and Graphites

Outstanding recent advances have been made in the development of high-density carbon and graphite, pyrolytic carbon and graphite, graphite whiskers, and so-called ductile graphite yarn and cloth. Solid carbons, with the exception of diamond, are made up of carbon atoms arranged in a hexagonal molecular pattern in parallel layers. In ordinary or amorphous carbon, the layers are randomly oriented to each other. In graphite the platelets are oriented so that alternate layers of hexagons are offset half the diameter of the hexagon from each other. In pyrolytic carbon and graphite, the individual crystallites are randomly oriented but tend to have their basal planes alined parallel to the surface of deposition. These oriented carbons are electrically and thermally anisotropic, and their conductivities may be almost 1,000 times greater along the layered planes than across them. Pyrolytic graphite is stronger, harder, denser and less permeable than ordinary graphite.

The oriented carbons are produced by the pyrolysis of a hydrocarbon gas. A base material is heated electrically above 1000° C and possibly as high as 2800° C in an evacuated chamber. Hydrocarbon gas is admitted at a constant flow rate. The molecules of gas are decomposed by the heat and the carbon adheres to the base surface.

Carbon yarn and cloth are manufactured by charring synthetic cellulosic filaments in an inert atmosphere after they have been spun and woven into final form (*2*). After charring, the filaments consist of plus 99.5 percent carbon and less than 0.5 percent ash. The tensile strength of the carbon filaments is about 30,000 pounds per square inch.

USES

Consumers of carbon and its products include electrical, automotive, and aviation equipment manufacturers, utility companies, steel, aluminum, and chemical producers; and manufacturers of specialized articles.

Coal and similar substances are used directly as industrial carbon in many applications. Specially prepared anthracite is used as potliner or cathode material for the production of primary aluminum. Anthracite also is used in place of coke in some smelting and carburizing operations. Special uses include battery boxes, granular carbon in telephones, and water filtering. Lignite has been used in the production of activated carbon by Atlas Chemical Co. in Texas, while Pittsburgh Chemical Co., Pittsburgh, Pa., uses bituminous coal for this purpose (*4*).

Coal coke is the principal elemental carbon commodity, and its use as a metallurgical fuel tops all other uses. About 50 million tons is consumed annually by the steel industry alone, where, in addition to being used as a fuel, coke may be classed as a reducing or carburizing agent in the making of steel. Coke fuel is used by other industries and in households for space heating. It also is used for making carburetted water gas, for making carbon bricks for lining furnaces, and for producing calcium carbide.

Petroleum coke probably is the most versatile of the mass-produced carbons, and is widely used because it is a plentiful source of good quality carbon at moderate price. Part of the production is used as a refinery fuel or as commercial fuel, often in powdered form. Its greatest use is as anode material, such as that used in the production of aluminum, and in electric-furnace operations. Another important use is for the production of calcium and silicon carbide. It is the preferred raw material for the production of manufactured graphite, and many types of shapes—block, brick, beams, slabs, and cylinders—are fabricated for use in many industries.

TABLE 6.—*Sales of carbon black for domestic consumption in the United States, by uses*

[Short tons]

Use	1959	1960	1961	1962	1963
Rubber	731,619	681,456	691,446	775,602	815,952
Ink	23,683	23,990	21,493	20,581	23,235
Paint	6,914	6,135	7,633	7,883	6,504
Miscellaneous	3,908	3,228	9,429	15,882	19,018
Total	766,124	714,809	730,001	819,948	864,709

Table 6 shows the average consumption of carbon black in the United States, 1959–63, by major uses.

The use of carbon black in rubber products, where its function is to impart toughness and improve the wearing qualities, far outweighs all others. Applications include tires, shoe soles and heels, hoses, gaskets, and conveyor belts. The average loading of carbon black in rubber, natural and synthetic, amounted to 740 pounds per long ton in 1963.

Carbon black is used as a pigment in inks and paints for newsprint, books, carbons, bags, resins, leather, lacquers, oilcloth and linoleum,

concrete, mortars, stucco, tiles, artificial stones for buildings and jewelry, shoe and stove polishes, and wood finishing. Low bulk, jet-black color, good suspension, ease of grinding, and low oil adsorption are prerequisites for these uses.

Miscellaneous uses include carbon brushes, electrodes, arc carbons, plastics, typewriter ribbons, and many other minor applications.

Activated carbon and chars are used for liquid-phase and vapor-phase adsorption. Liquid-phase adsorptive carbons are used in refining sugar, edible oils and fats, certain foodstuffs, and alcoholic beverages; in processing chemicals and pharmaceuticals; in reclaiming solvents; in recovering adsorbed substances; in purifying water; and as a catalyst. Vapor-phase adsorptive carbons are used for the removal of solvent vapors, odors, and other impurities in air and gases. Most of the bone char production is used to purify cane sugar solutions. After saturation with impurities, the bone char is washed free of sugar and recalcined at about 500° C with restricted air, which destroys the impurities and restores the absorbing power of the carbon.

Manufactured carbon and graphite products include electrodes, anodes, arc carbons, structural and speciality carbons, and brushes for electric generators and motors. Metallurgical applications include furnace linings, trough and tank liners, mold plugs, stool inserts, fluxing tubes, casting molds, sintering boats and trays, and crucibles for induction and arc melting (*13*). Some other industrial uses are welding products, impervious pipe, fittings, valves, pumps, towers, heat exchangers, and tubes. Lubricants, greases, fabrics, piston rings, switch and circuit breaker contacts, anodes and grids for electronic devices, thrust rings for automobile clutches, and moderating material in reactors are among the many special uses.

Carbon also is used in the manufacture of chemical compounds, activated carbon, and manufactured carbon and graphite articles. Chemical compounds are principally carbon disulfide, the carbides of calcium, boron, and silicon, and pigments and dyes. Carbon disulfide is used primarily as a solvent in the vulcanization of rubber and the manufacture of viscose silk or rayon; and in the manufacture of carbon tetrachloride. Calcium carbide is used in the fixation of atmospheric nitrogen and in the production of acetylene (for use as a chemical raw material and in steel-cutting and welding torches). Silicon carbide is used as an abrasive, in crucibles, as resistor rods, and as a superrefractory. Boron carbide is used principally as an abrasive.

BYPRODUCTS AND COPRODUCT RELATIONSHIPS

Coal, when coked, produces about 10,000 cubic feet of valuable gas per ton of coal. The gas has a heating value of about 550 Btu per cubic foot. The principal use for coke is in the steel industry, but it is also important in smelting of nonferrous metals. Water gas, produced from coke and enriched with gases from cracked oil (called carburetted water gas) has served as fuel for residential and industrial consumers. Water gas may be used also for the synthesis of motor fuels, methanol, and other chemicals.

Ammonia, coal tar, and light oils are important byproducts of coke production. Ammonia is used for chemicals and fertilizers. Coal tar is a mixture of many organic chemical compounds which have formed the basis of the aniline and dye industries. The light oils consist of benzene, toluene, xylene, and naphtha, which are the raw materials used for the production of many organic chemicals.

Petroleum coke is a byproduct of coking processes in the cracking of petroleum stocks—usually residual oils. The primary purpose of the process is the production of coker gas oil which can be charged to catalytic or thermal crackers for producing lower boiling fuels, principally gasoline. All petroleum refining processes do not produce petroleum coke, particularly those that produce residual fuels and lubricating oils as an end product.

Carbon black was once produced almost entirely from sour natural gas, which had no other market. Today, the major part of domestic carbon black is made from liquid petroleum fractions.

ALTERNATE MATERIALS

There are no satisfactory substitutes for carbon in its major applications. Manufactured and natural graphite vie with each other in many uses, but the manufactured variety is unsuited for some uses, especially where large natural flake is required as in graphite crucibles. For use in nuclear reactors, manufactured graphite is preferred because of its greater purity and because it can be formed more easily into special shapes.

Silica gel, fuller's earth, activated clay, and activated alumina are used in place of activated charcoal and chars in some types of liquid- and gas-phase adsorption. Carbon may be displaced if the other materials prove to be more suited for the removal of a particular impurity. However, changes in established adsorption systems or adsorbents in the principal applica-

tions are slow to develop even though a new material may prove to be more efficient.

RESERVES

Industrial carbon can be produced from coal, petroleum, other mineral hydrocarbons, and many vegetative materials. Reserves, both foreign and domestic, are large and in the case of vegetable material such as trees, they are replaceable and thus incalculable. The United States has about one-third of the estimated coal reserve of the world, one-ninth of the proved petroleum reserve, and about one-third of the proved gas reserve. Data on fossil fuel reserves are shown in chapters on the fuel minerals.

SOURCES OF STATISTICAL INFORMATION

Annual data on the quantity and value of production and sales of petroleum coke, metallurgical coke, coal and lignite, natural gas, and carbon black are obtained by canvass of domestic producers and published by the Bureau of Mines. Additional information is available from the Departments of Labor and Commerce, the Federal Power Commission, the Interstate Commerce Commission, and State mining agencies, in addition to sales agents, dealers, distributors, railroads, traffic associations, and consumers. Much information is available from publications of the Petroleum Institute, the American Gas Association, and the American Carbon Committee. With the exception of raw materials for carbon black no breakdown is given for quantities used as industrial carbon. No canvass of users is made.

World production and trade data are compiled from data collected by the U.S. Department of State and U.S. exports and imports are compiled from data supplied by the U.S. Department of Commerce.

PRODUCTION, CONSUMPTION, AND TRADE

Data on the production and consumption of carbon for all industrial uses are not published as such. Published production and consumption data on the major raw materials—coal, coke, and charcoal—include uses other than industrial carbon. Table 7 gives estimated consumption of carbon by uses in the United States in 1963. The data on silicon carbide, calcium carbide, and carbon disulfide were estimated from the quantity of carbon materials required to manufacture the quantity of these chemical compounds produced in the United States. The estimates on anodes and electrodes were published in the trade journals. Data on carbon black were published by the Bureau of Mines and the data on activated carbon and chars were obtained from the Bureau of the Census.

TABLE 7.—*Estimated consumption of industrial carbon in the United States in 1963, by major uses*

[Short tons]

Carbon containing product	Carbon used in manufacture
Electrodes:	
Anodes (for aluminum production)	1,500,000
Cathodes (for aluminum production)	100,000
Other electrodes	590,000
Carbon black:	
Rubber	815,000
Ink	23,000
Paint	6,500
Miscellaneous	19,000
Silicon carbide	60,000
Calcium carbide	416,000
Carbon disulfide	41,000
Activated carbon	72,000
Bone chars	11,500
Miscellaneous	170,000
Total	3,824,000

Data on world production and consumption of industrial carbon are not available and data on U.S. imports and exports are not completely reliable. Imports are generally small, and known exports consist chiefly of carbon black, petroleum coke, and anthracite coal. A trade journal estimated that 250,000 tons of petroleum coke per year is exported to Canada for use in the production of primary aluminum (*17*). It is estimated that 150,000 tons of anthracite per year is exported to Canada for use as cathodes in the production of aluminum.

Production and shipments of carbon black in the United States in 1963 by grades are shown in table 8, and the production by States and districts is shown in table 9.

[1] Detail will not add to totals because some producers operated in more than 1 area.
[2] Included with "Texas: Rest of State" to avoid disclosure of individual company confidential data.

World production of carbon black was not known in 1963. Known producers were United States, United Kingdom, West Germany, Rumania, Japan, Brazil, France, Yugoslavia, Canada, China, and Italy. The first three were the leading producers. The rising demand for rubber in foreign countries has increased demand for carbon black (*5*). This demand has been met in the past by exports from the United States, but in recent years, the number of carbon black plants in foreign countries has been rising. The loss in U.S. exports is partially offset by the fact that almost all of the new foreign plants are financed with American capital.

Charcoal and chars were imported from Mexico, Japan, Canada, Ceylon, United Kingdom, Netherlands, Egypt, Portugal, France, and Jamaica. Carbon black was imported principally from Canada with small quantities coming from West Germany, United Kingdom, Switzerland, Netherlands, and Japan.

Charcoal and chars were exported to 55 countries, principally Mexico, Canada, Argentina, Brazil, Venezuela, France, Italy, West Germany, Belgium-Luxembourg, United Kingdom, Sweden, Japan, India, Republic of South Africa, and Australia. Carbon black was exported to over 45 countries on 6 continents shown summarized in table 10.

Ad valorem tariff rates effective in 1963 were bone black and bone char, 20 percent; artificial graphite, 5 percent; calcined petroleum coke, 15 percent; carbons and chars, activated or not, 19 percent; acetylene black, 5 percent; gas black pigments, 5 percent; and liquid black pigment, 10 percent.

Total	370, 928	35, 447

STRATEGIC CONSIDERATIONS

The United States is self-sufficient in all forms of carbon raw material. The supply of coal and woody materials is virtually unlimited and the supply of petroleum and natural gas, although more limited than the others, is adequate.

Present production and need for petroleum coke as a raw material for industrial carbon is below actual or potential capacity. Many refineries do not produce marketable coke either because they do not have coking facilities or because there is no readily available market. The increasing use of petroleum liquids in the production of carbon black makes that portion of the carbon industry subject to any wartime shortage in the petroleum industry. Natural gas, the other source of carbon black, is not affected by wartime demands to the extent that petroleum is. A loss in carbon black production due to petroleum shortages might be offset by increased production from natural gas.

PRICES

No formal data are published on petroleum coke prices. Prices taken from articles in trade journals range from $10 to $20 per ton and are subject to negotiation by buyer and seller. Prices paid to the petroleum refiner depend on plant location, quality and quantity of the coke, and other factors. In 1963, the average value of coke made from coal was $15.38 per ton.

Prices of carbon black are given in table 11. The average value of natural gas used in the production of carbon black during 1963 was 12.70 cents per thousand cubic feet and the value of liquid hydrocarbons used was 6.66 cents per gallon.

TAXES

No special taxes are imposed on the carbon industry, other than those that are applied to the raw materials: Anthracite, coal, petroleum, and natural gas.

RESEARCH

Research on manufactured carbon by government and private industry is directed toward fundamental studies of the physical and chemical properties of carbon, and research to improve present applications and develop new uses.

Research on basic properties has involved kinetics, electron spin resonance, atomic dislocations, surface reactions, catalytic properties, and radiation effects. Research also included the mechanism of carbon formation, high-temperature properties, mechanism and rate of graphitization, heat treatment effects, and electronic properties.

With the exception of special carbons, techniques of manufacturing industrial carbon appear to be fairly stabilized, and most research in this area is directed toward improving present systems utilizing carbon end products. In addition, research is conducted on the carbon product to improve performance or to develop new uses.

Manufactured carbon and graphite have great high-temperature strength, extreme resistance to thermal shock, high thermal conductivity, and relatively low density. These properties have led to its consideration as a material for use in space vehicles. However, heterogeneous physical properties and structure in single specimens coupled with a high rate of oxidation at elevated temperatures have presented problems. Much of the present research is directed toward overcoming these obstacles.

The intense research on the physical and chemical properties of oriented carbon and graphite reflects a desire to use these materials in space applications. The Federal Government, through research contracts with private industry, is conducting extensive research on all types of manufactured carbon and graphite with particular interest on those materials with possible applications in missiles, high-speed aircraft, and space vehicles. A great part of the research and development sponsored by the Government is on the refractory properties of graphite and its possible use at temperatures above 3,000° C.

Government agencies that are conducting noteworthy research on some applications of carbon include the various laboratories of AEC—Argonne, Brookhaven, and Oak Ridge National Laboratories—and the Bureau of Standards.

Firms that have had a major role in the Government program to improve carbon and graphite products, including pyrolytic graphite, are Union Carbide Corp., Carbon Products Division, Lawrenceburg, Tenn.; General Electric Co., Hanford, Wash., and Schenectady, N.Y.; Lockheed Missiles and Space Co., Palo Alto, Calif.; Raytheon Manufacturing Co., Waltham, Mass.; Bell Telephone Laboratories, New York, N.Y.; Atomics International, a division of North American Aviation, Canoga Park Calif.; and Westinghouse Electric Co., Pittsburgh, Pa.

Among other companies that maintain staffs for research on carbon and graphite (and their principal field of research) are the following:

Company and location:	*Field of research*
Stackpole Carbon Co., St. Marys, Pa.	Carbon and graphite uses.
Pure Carbon Co., St. Marys, Pa.	Do.
Atlas Powder Co., Wilmington, Del.	Activated carbons.
Darco Experimental Lab., Marshall, Tex.	Do.

Company and location—Con.	*Field of research*
The Carborundum Co., Niagara Falls, N.Y.	Carbides, Superrefactories.
C. L. Mantell & Asso., New York, N.Y.	Activated carbon, electrodes.
Speer Carbon Co., St. Marys, Pa.	Nuclear and electrode graphite.
Asbury Graphite Mills, Inc., Asbury, N.J.	Blacking and plumbago.
Eagle Pencil Industries, Inc., Danbury, Conn.	Carbon in rubber and pigments.
Columbian Carbon Co., New York, N.Y.	Uses of carbon black.
Great Lakes Carbon Co., New York, N.Y.	Manufactured graphite.
United Carbon Co., Houston, Tex.	Carbon black.
Joseph Dixon Crucible Co., Jersey City, N.J.	Graphite refactories and crucibles.
Acheson Colloids Co., Port Huron, Mich.	Pigment carbon black.

The American Carbon Committee is composed of members who represent university, government, and industrial laboratories which study carbon by physical and chemical methods. The interests of the members encompass manufacture, properties, and use of carbonaceous materials. Publication and discussion of research results are promoted through conferences on carbon convened at 2-year intervals. The Fifth Carbon Conference, convened at Pennsylvania University June 19–23, 1961, resulted in publication of 2 volumes containing 157 papers (*2*).

The Society of Chemical Industry, London, England, is the British counterpart of the American Carbon Committee and periodically holds conferences on the industrial uses of carbon and graphite (*20*).

OUTLOOK

The short- and long-term supply outlook for industrial carbon required by the U.S. domestic economy does not pose any difficult problems. The supply of all types of raw materials is more than adequate and it would take a large increase in consumption to create any shortage in raw materials.

Consumption is not expected to increase greatly but should at least keep pace with the growth of the national economy and may better the gross national product rate. The great amount of current research may develop new uses that could change present consumption trends. This is particularly true of carbon black whose reinforcing properties may have many other applications besides rubber. However, the use of industrial carbon in special applications, such as space vehicles or atomic reactors, is not expected to increase overall consumption greatly. Such uses receive spectacular publicity but they do not involve large quantities of carbon.

Production facilities for all kinds of carbon raw materials are adequate. The expansion of carbon black production plants in foreign countries should cut domestic exports, thereby making domestic plants more than adequate for domestic needs. Furnace methods of producing carbon black will continue to displace the less-efficient channel process. The capacity of manufactured carbon and graphite plants is adequate for present needs.

PROBLEMS

Sources of statistics are inadequate to determine precisely the requirements, supply, resources of industrial carbon, and the quantities and qualities required by different consumers. Ample supplies of raw materials have created a lax situation in the statistical canvassing of the industry.

One of the major problems of the carbon industry is to determine the degree of interchangeability of the various raw materials. Most of the raw materials are used for fuels; often only a small portion of the production is used for industrial carbon. Future demand for some of these materials in other markets may force carbon manufacturers to develop new sources.

A major technologic problem is how to improve recovery of carbon black in the furnace method of manufacture. The operating efficiency for the furnace method is about 50 percent for oil feed and about 20 percent for gas feed.

CEMENT

By William R. Barton [1]

PORTLAND cement concrete is the most widely used construction material in the world. In the United States, almost twice as much concrete is used as all other structural materials combined.

The United States produces and consumes more than 16 percent of the world's cement. Our economy requires almost 2 barrels (all barrels in this report are 376 pounds each unless otherwise noted) of cement per person with a total 1963 value of $1.2 billion. The portland cement industry in 1963 comprised 181 producing plants in 40 States and Puerto Rico with a total production capacity of 478 million barrels.

A domestic cement industry has become almost a prerequisite in any country where industrialization is undertaken. As result many under-developed nations have established indigenous cement industries. Therefore, while U.S. cement use has consistently increased, it is a decreasing percentage of total World demand.

New production machinery and methods have constantly lowered cement production costs. At the same time, more rigorous specifications for cement and more sophisticated consumer tastes and needs have proliferated the special types of cement on the market. New automated bulk transportation equipment and local market distribution centers permit the industry more flexibility in meeting customer needs.

Continued growth of the cement industry is forecast as population increases generate a need for more highways, schools, dams, housing, and industrial plants. Continued technological innovations will hold the cost of cement at favorable levels in relation with competitive building materials.

BACKGROUND

As early as 2500 B.C., clay was added to lime mortar to make hydraulic cement in the Near East. The word "cement" was first used more than 2,000 years ago by the Romans to describe impure limes used as mortar in stonework. With the decline of the Roman Empire, the secret of cement manufacture was forgotten, and it was 1756 before examination of an ancient Latin manuscript by English engineer John Smeaton, led to the rediscovery of Roman hydraulic cement, which was superior to the straight lime mortars then in general use. The new natural cements soon became popular in England, France, and other European countries. In 1824 Joseph Aspdin, an English bricklayer and stonemason, obtained a patent for making "Portland cement," so called because it resembled stone quarried on the Isle of Portland. Essential improvements in the manufacture of modern portland cement are the scientific blending of raw materials to a uniform composition and the burning to incipient fusion rather than simple calcining as in the case of natural cements. By 1850 portland cement began to displace natural cement in all European markets.

The cement industry in the United States began early in the 19th century when a construction material better than quicklime was needed for masonry work and locks of canals in New York, Pennsylvania, Maryland, Illinois, and Kentucky. Beds of argillaceous limestones in each State were found to possess good hydraulic properties when calcined. Natural cements equal in quality to European cements were made from the limestones and used in constructing the Erie, Chesapeake and Ohio, and many other well known canals. In 1875, the first attempts to produce portland cement in the United States were made at some of the natural cement plants. Throughout the 19th century, natural cement production continued to

[1] Commodity specialist.

grow despite imports of European portland cements and the competition from the struggling portland cement branch of the domestic industry. In the larger cities, brick and stone buildings were erected with natural cement mortars whereas quicklime formerly had been used. In 1899, there were 76 cement plants that produced 10 million barrels of natural cement.

By 1895, production of portland cement had risen to 1 million barrels with 40 percent produced in rotary kilns using oil as a fuel. In 1899, there were 36 plants producing portland cement, and 66 percent of the 6 million barrels produced was from plants using rotary kilns. The successful application of powdered coal as a fuel for rotary kilns gave great impetus to the rise of the portland cement industry. In 1910, the number of portland cement plants had increased to 111, and over 76 million barrels were produced, practically all in rotary kilns.

After 1899, many natural cement plants were converted to portland cement plants, and since 1910 only a few plants have continued to produce natural cements.

From 1910 until 1929 the portland cement industry expanded until there were 88 companies with 168 plants. The depression of 1929 stopped further growth of the portland cement industry for 17 years; 20 companies ceased operation, and 16 others were absorbed by other companies.

After World War II, expansion resumed and by 1954, 75 companies operated 157 plants in the United States. Since that time increasing competition has resulted in numerous consolidations so that while the number of operating plants increased to 181, in 1963, the number of operating companies was reduced to 52. Seven firms operate single plants making natural, slag, or portland-pozzolan cement (5 of these are also included in the list of 52 portland cement companies).

SIZE, ORGANIZATION, AND GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

Cement is produced in many countries throughout the world. Most of the highly industrialized nations export varying quantities of cement to the less developed nations. A domestic cement industry has become almost a prerequisite in any country where industrialization and attendant heavy construction projects are undertaken. As a result, in the past 10 years many of the newly constituted nations have created their own cement industry with the aid of capital investment, loans, or grants from business or governments of highly developed countries.

The United States is the largest single cement producing and consuming country in the world, but owing to rapid rises in overseas demands our share of world production and consumption has declined from more than 20 percent in 1958 to about 16 percent in 1963.

Value of sales at cement plants in the United States was $1.2 billion in 1963, representing one of the largest segments of the Nation's mineral industry. U.S. imports and exports of cement are relatively unimportant, rarely exceeding 2 percent of the domestic production, although locally for short periods imports can severely affect the market.

Of the 52 companies producing portland cement in the United States during 1963, 13 were subsidiaries of or affiliated with firms not engaged primarily in cement manufacture. These 13 subsidiary cement firms comprised 28 percent of U.S. portland cement production capacity. Four of these subsidiaries were among the 10 largest cement companies. In 1963, the 10 largest producing companies owned 57 percent of total U.S. cement capacity, and the 18 largest accounted for 79 percent of the national total.

In addition to the 181 portland cement plants with a total capacity of 478 million barrels, approximately 200 distribution centers were operated by the cement manufacturers for efficient marketing in major domestic consuming centers.

Until 1917, world production of cement was concentrated in a few European countries and the United States. Since then local cement industries have germinated in all parts of the world, and in 1963 production was reported from more than 90 countries in 6 continents.

In the 19th century, the domestic cement industry was concentrated in New York and Pennsylvania, close to the large population centers. As the country grew and construction requirements spread to other sections of the Nation, the cement industry expanded into other States. In 1963, there were 181 producing portland cement plants in 40 States and Puerto Rico. Only Alaska, Nevada, North Dakota, the District of Columbia, Delaware, New Jersey, Connecticut, Rhode Island, Massachussets, Vermont, and New Hampshire did not have production facilities, but a plant was under construction in Nevada and one was being planned in Alaska. Leading producer States in 1963 were California, 13 plants; Pennsylvania, 22 plants; Texas, 16 plants; Michigan, 9 plants; and New York, 12 plants. The 478 million barrels of portland cement production capacity in 1963 was 30 percent in the Eastern United States, 50 percent in the Central States,

and 20 percent in the western part of the country. Capacity was increasing at a relatively more rapid pace in the Central and Western States in line with their relatively more rapid rate of population gain.

In 1963 the U.S. portland cement industry operated at 73.4 percent of capacity. This apparent under utilization of capacity was not as great as it appears due to geographic inequalities, seasonal fluctuations, and obsolete equipment still in use but being operated at high cost and with only a short remaining useful life span.

In general, cement markets have been local, that is, within a radius of 150 to 300 miles from the producing plant. However, with increased use of high-capacity, automated barges and trucks and market center sales and distribution terminals, some producers have expanded their market territories. A company on the Hudson River, for example, has one terminal situated 1,000 miles from its production plant.

An excellent reference map titled: "Portland Cement Plants U.S., Canada, & Mexico" is published biennially by Pit and Quarry Publications, 431 South Dearborn Street, Chicago, Ill. The map shows locations of existing plants and distribution centers and also those under construction. Plant ownership, capacity, and type of production process are also identified for each plant.

DEFINITION OF TERMS, GRADES, AND SPECIFICATIONS

Cement, literally, is any substance used to make bodies adhere to each other and includes a great diversity of natural and synthetic materials including asphalt, glue, epoxy resin, lime, plaster, paste, and portland cement. Hydraulic cements are those which have the property of "setting" or hardening under water; nonhydraulic cements do not set under water. This discussion is confined to calcareous hydraulic mineral cements such as portland, portland-slag, natural, masonry, pozzolan, and slag.

Specifications for cements were recommended by the American Society of Civil Engineers in 1885 and accepted by many consumers as standard. Much of the early testing of portland cements was done by government and city engineers using the German standard of 227 pounds per square inch tensile strength after 28 days as a guide. Specifications issued by the American Society for Testing and Materials (ASTM) in 1917 were accepted as U.S. Government standards. Since then, revisions have been made from time to time as various types of cement were produced to meet definite requirements. The latest ASTM cement specifications are too voluminous to include in this report, but the important ones which have been promulgated are listed for each type of cement and may be obtained from the American Society for Testing and Materials.

Clinker is the term used for the pea to golf ball size, partially fused lumps formed in the kiln during cement manufacture by burning a proportioned mixture of raw materials. Chemically, the clinker consists of varying proportions of tricalcium silicate ($3CaO \cdot SiO_2$ abbreviated to C_3S), dicalcium silicate ($2CaO \cdot SiO_2$ or C_2S), tricalcium aluminate ($3CaO \cdot Al_2O_3$ or C_3A), tetracalcium aluminoferrite ($4CaO \cdot A1_2O_3 \cdot Fe_2O_3$ or C_4AF) and minor calcium sulfate ($CaSO_4$), magnesia (MgO) lime (CaO) and various alkalies depending upon the raw materials used, production flowsheet, and type of cement being manufactured.

Portland cement is produced by burning a finely ground mixture containing approximately 75 percent calcium carbonate, 4 percent magnesium carbonate, 14 percent silica, 5 percent alumina, and 1 percent iron oxide at about 2,700° F. The magnesium carbonate is not necessary to the composition but usually occurs mixed with the calcium carbonate in nature. The remaining 1 percent may include impurities such as sulfur, and alkalies. Although limestones and shales or clays are the commonly used raw materials, various combinations of economically available materials are used as may be necessary to make a proper composition. Uniformity of the final product is controlled by careful chemical analysis of the mixture. The clinker kiln product is ground to form the powder sold as portland cement.

Most portland cements approach their ultimate strength in 1 year and reach 65 to 75 percent of their ultimate strength in 7 days; the *high-early-strength type* reaches almost one-half of its ultimate strength in 1 day. In 1940, ASTM grouped portland cements under five types, based partly upon the proportions of tricalcium silicate, dicalcium silicate, and tricalcium aluminate in the cement. Specifications for Type I, general-purpose cement, and Type II moderate-heat cement, are so similar that many companies make only one type that will meet the requirements of either. Type III, high-early-strength cement containing a greater quantity of tricalcium silicate, is made by many companies for use where time cannot be allowed for Type I or II to develop strength. Types I, II, and III together constitute more than 97 percent of all the portland cement in the United States. Type IV, low-heat cement containing less tricalcium silicate and tricalcium aluminate and Type V, high-sulfate resistant cement containing the least amount of trical-

cium aluminate, are usually made only upon order (ASTM Specification C 150–63).

Natural cements, sometimes called Roman cements in Europe, are produced by calcining an impure, argillaceous limestone or dolomitic limestone containing from 15 to 40 percent silica, alumina, and iron oxide at a comparatively low temperature, about 1,400° F, at which decarbonation but no fusion takes place. The burned mass will not slake if water is added, but when ground to a powder it will harden rapidly when mixed with water. Variations in the chemical composition of the limestone bed, used at any particular plant, are reflected in the composition and quality of the finished cement. Natural cements acquire most of their ultimate strength in 5 years and only one-eighth of their ultimate strength in 7 days (ASTM Specification C 10–62 T).

Masonry cements are mixtures of portland or natural cements, finely ground limestone or lime, and a plasticizer additive that are prepared for use as a mortar for laying brick or other masonry work (ASTM Specification C 91–63).

Pozzolan cements are produced by pulverizing mixtures of slaked lime or portland cement clinker with volcanic ash, granulated blast furnace slag, or other pozzolanic material. These *pozzolanic materials*, or *pozzolans* as they are sometimes called, are siliceous or siliceous and aluminous materials, which in themselves possess little or no cementitious value but will, in finely divided form and in the presence of moisture, chemically react with calcium hydroxide at ordinary temperatures to form compounds possessing cementitious properties. These include such natural materials as some of the diatomaceous earths, opaline cherts and shales, tuffs, and volcanic ashes or pumicities; and such artificial materials as precipitated silica and some blast furnace slags and fly ashes (ASTM Specifications C 340–63 T).

Pozzolanic materials also are used as additives to finished portland cement. Some diatomaceous earths have been used in such small quantities as 3 percent of the weight of the cement for improving the workability and preventing segregation of the concrete. In proportions of 10 to 35 percent of the weight of the pozzolan and cement used, the heat of hydration may be less than for some portland cements, and the permeability of concrete in lean mixes may be reduced (*16*).[2]

Slag-lime cements are made by pulverizing mixtures of slaked lime and granulated basic blast-furnace slag. These cements are sometimes considered pozzolan cements even though granulated basic blast-furnace slag contains silicates of calcium and possesses some cementitious value without the addition of slaked lime and therefore is not a true pozzolanic but rather a latent hydraulic material. (ASTM Specification C 358–63 T).

Portland-blast furnace slag cement is sometimes classified as a pozzolanic cement and is made by grinding together portland cement clinker and granulated slag in proportions of about 35 to 50 percent cement and 50 to 65 percent slag (ASTM Specification C 205–63 T).

Air-entraining cement are cements to which an air-entraining agent has been added during grinding. Alternatively, air-entraining agents may be added to a concrete mix instead of being interground with the cement (ASTM Specification C 175–63).

High-alumina cement or aluminous cement is manufactured by burning a mixture of limestone and bauxite containing about 30 percent alumina compared with 5 percent alumina in an ordinary portland cement raw mix. The resultant cement is black in color and has a high-early-strength. The main constituent is monocalcium aluminate ($CaO \cdot Al_2O_3$). There is no American standard specification. The specifications for portland cement are frequently used pending formulation of standards.

Concrete is defined as artificial stone made by mixing cement and sand and gravel, broken stone, or other aggregate. The materials are mixed with sufficient water to cause the cement to set and bind the entire mass (ASTM Specification C 94–63).

A bag of cement is theoretically equal to 1 cubic foot. In the United States for portland cement this is standardized at 94 pounds and for most prepared masonry cement at 70 pounds.

A barrel of cement equals four bags, or 376 pounds of portland cement and 280 pounds of prepared masonry cement.

TECHNOLOGY

Geology and Raw Materials

It requires approximately 3,200 pounds of raw materials (not including fuel requirements) to make 1 ton of portland cement. Depending upon the type of cement being manufactured and the composition of available raw materials, a variety of components are blended to achieve the proper composition of mill feed. For standard Type I portland cement a typical raw blend analysis would be as follows: $CaCO_3$, 75.8 percent; SiO_2, 14.1 percent;

[2] Italicized numbers in parentheses refer to items in the list of references at the end of this chapter.

$MgCO_3$, 3.5 percent; Al_2O_3, 4.2 percent; Fe_2O_3, 1.6 percent; and alkalies, 0.8 percent.

Theoretically, a large number of mineral raw materials could be blended to achieve the desired raw mix composition, but in practice a comparative few are actually used.

Argillaceous limestone, or "cement rock" as it is often called, close to the desired lime-silica-alumina proportions, is combined with minor quantities of other materials to produce the proper mixture at almost one-fourth of the cement plants.

At others, the necessary lime is supplied by limestone, marl, marble, or oystershell and the alumina and most of the silica and iron oxide by clay, shale, blast-furnace slag, schist, or bauxite. If additional silica is needed, it is obtained by adding quartz sand or sandstone, and additional iron oxide by adding iron ore or iron rich residues.

Sometimes all the raw materials are not available at one place so the supply of the primary raw material, "cement rock" or limestone, usually determines plant location. If suitable clay or shale is closely associated, as is often the case, so much the better.

The major raw materials mentioned are all marine sedimentary in primary origin and an intrinsic property of such rock is relatively uniform chemical and physical character over areas of wide lateral extent. Such materials usually occur flat lying or only moderately inclined from the horizontal plane. These geological factors result in widespread distribution of raw materials usually amenable to large-scale, low-cost open-pit mining (*4, 5*).

Mining

Cement is such a low-priced commodity that every economy of rock-breaking, transportation, grinding, and calcining must be utilized. The rock is recovered from large quarries (or, in some instances, from underground mines), or the marl or shell is dredged from excavations or from offshore deposits.

Large capital investment for cement plants demands that reserves sufficient for many years large-scale operations be proven prior to installation. During mining, every effort is made to design the layout to utilize the largest, most economical machinery. For example, one new plant uses optimum blasting practices to break a week's rock requirements (60,000 tons) with each shot, and employs a 9-cubic yard electric shovel to load 45-ton capacity diesel trucks which haul the broken rock to a 54-inch gyratory primary crusher. The rock is then further reduced in smaller gyratory crushers, hammermills, or other breakers to about ¾-inch size. Later, upon withdrawal from storage piles, the rock is further reduced to less than ¼-inch size in similar tertiary crushing units.

Preparation of Kiln Feed

As the crushed raw materials arrive at the grinding mills, they are automatically weighed and selectively introduced into the plant flowsheet by remotely controlled (in some cases by a computer) proportioning feeders. This system compensates for raw material variables and maintains the uniform feed essential to quality control. The raw grinding unit consists of tube or ball mills in which the mixed raw materials are comminuted to very fine particle sizes, usually 85 percent through 200-mesh or finer.

A few plants use flotation methods to remove objectionable impurities such as excessive silica or silicates from raw materials, enabling more efficient use of quarried materials.

Two different processes that vary in method but not in principle are used in manufacturing cement—the dry process and the wet process. In the former, the material is dried—in most plants during raw grinding—and the mixture is fed into the kilns in a dry state; in the latter, a slurry of controlled consistency is burned. The principal advantages claimed for the wet process are simpler blending of the ground raw materials and elimination of the drying of moist raw materials. It also requires less power than dry grinding. Advantages claimed for the dry process are greater kiln fuel economy and shorter, less expensive kilns. In the United States about 60 percent of installed capacity is wet process and 40 percent dry process.

Kiln Operation

Rotary cement kilns are among the largest pieces of moving machinery used in any industry; kilns up to 600 feet long and 20 feet in diameter are used in the United States (and larger ones are planned). In Japan and the Soviet Union kilns over 600 feet in length are in operation. Cement kilns are steel cylinders lined with the necessary refractories, inclined slightly, and rotated slowly. The fuel, which may be powdered coal, oil, or gas, is blown into the kiln, creating tongues of flame reaching 30 to 50 feet into the kiln. The raw mixture is fed into the upper end of the kiln automatically. Hot gases from the flames in the lower end of the kiln pass over the raw mixture, expelling the moisture and converting carbonates to oxides. As the material descends slowly in the kiln, it reaches the so-called burning zone in the lower one-third of the kiln, where the material reaches the point of incipient fusion, and complex silicates and aluminates are formed. When it emerges from the kiln, it is a new sub-

stance in the form of hard, fine-grained balls called clinker, which is passed through a cooler and sent to large storage sheds.

Cement clinker is relatively inert after it has cooled and may be stored for months without deterioration.

One of the major factors in maintaining a low price for portland cement has been the continuing improvement in kiln design from the original 50-foot length to the present size. Waste heat from the kilns was utilized in many ways in attempts to reduce fuel consumption at the plants. Emphasis in recent years has been placed on better utilization of the heat within the kiln by nodulizing, preheating the kiln feed in the exhaust of the kiln, and preheating the fuel and air with recovered heat from the clinker. Current kiln design favors internal heat exchangers such as a chain zone near the upper end of the kiln by which heat is withdrawn from the kiln exhaust gases by "curtains" of stainless steel chain and transferred to the raw feed as it passes through the hot metal curtain.

When rotary kilns were first used over 2 million Btu were required per barrel of cement produced. Today's average is about 1 million Btu, and a plant at Superior, Ohio, reports 700,000 Btu per barrel using a chain zone.

In recent years, air pollution from plant exhaust stacks became a major factor in many areas, and the dust nuisance of formerly isolated cement plants became part of an expanding problem. More complete combustion has solved part of the problem and elaborate dust collection systems have been incorporated in renovation plans of many plants. Cyclone dust collectors and electrostatic precipitators are now integral parts of most plants, and various ways have been devised to return the recovered dust to the kiln or feed circuit without detrimental effect upon the chemical balance of the mixture.

Control and instrumentation of kilns is also making great strides. Computer control and complete closed loop operation, are in practical use at some plants and being considered or experimented with at many more. Sonic, gamma-ray, and electronic indicators are in general use, and X-ray spectrography providing analyses in a few minutes that used to take 6 or 8 hours permits immediate and accurate plant adjustments for quality control.

Clinker Grinding

When clinker is taken from storage to be ground into cement, approximately 4 to 6 percent of gypsum regulator is added. "Finishing" mills, usually ball mills, grind the clinker to extremely fine particle sizes, over 90 percent through 325-mesh usually expressed in square centimeters of surface per gram of cement. The finished cement is a powder finer than flour or face powder when it leaves the mill.

USES

Portland cement has little utility alone but rather is the material which, in the presence of water, binds minerals aggregate into concrete or as a constituent of mortar will hold building blocks or bricks together.

The addition of water causes a hydrous gel from which various compounds crystallize and interlock giving the hard "set."

The early uses of portland cement concrete in the United States were for foundations, retaining walls, dams, piers, bridge abutments, sidewalks, and for highway and street pavements. All of these were uses where compressive strength and durability were the primary requirements. Many other uses were added when reinforcing steel was imbedded in the concrete to compensate for lack of tensile strength. Buildings of all sorts, residential, commercial, and noncommercial, such as schools and auditoriums, are now built of concrete. The use of lightweight concretes and prestressing techniques has extended the use of concrete to thin-shell roofs with unsupported spans of great lengths and to lightweight bridge decks. Soil cement, made by mixing dry cement with surface soils and subsequently wetting and tightly compacting the mixture, is widely used to pave roads, streets, airports, and parking areas in cases where the strength of a regular pavement is not required.

Excessive expansions of certain concrete structures have been observed, whereas other structures made with concrete containing the same cement but different aggregates have remained in good condition. On the other hand, other concrete structures with poor aggregate, but a different cement, had remained in excellent condition. Some constituents in certain cements react under given conditions with some constituents in certain aggregates. Tests have indicated that the constituent in the cement responsible for the action is the alkali, either Na_2O or K_2O. Laboratory investigations have confirmed the theory that interaction of some of the siliceous constituents of the aggregate with the alkali in the cements causes an alteration of the aggregate material and expansion of the concrete after setting. The substitution of finely pulverized reactive silica or pozzolanic material for part of the cement provided a large area of reactive surface to reduce an initial high alkali concentration. Several other remedial measures, including control of the alkali content of the cement, have been used to avoid undue expansions when alkali-reactive aggregates are

used, but no complete solution has been found.

Increasing variations of cement have come into special use such as white, high-alumina, expansive and oil-well grout cements.

Concrete made with heavy aggregates such as barite or iron ores is in common use at atomic plants where radiation protection is required. Such concrete will shield persons from the gamma and beta irradiation which is the result of the disintegration of radioactive materials. Research also has been conducted on cements of special composition which may have particular utility in radiation shielding (*10*).

New lower cost or improved methods of casting concrete such as prestressing, slip-forming, precasting, and modular construction have made portland cement concrete of increasing interest to builders and architects who are continually creating new free-form and sculptured finish designs, making concrete structures more diverse and attractive in aspect.

BYPRODUCTS AND COPRODUCT RELATIONSHIPS

As manufactured by most companies, there are no major byproducts of cement, although prepared masonry cement mixtures are a common coproduct made by mixing finished cement with ground lime or limestone. In preparing a mixture for the kilns, especially when flotation beneficiation is employed, several types of material may be rejected from the kiln mixture. They may be either sent to waste or, if a market can be found, sold as a byproduct of the manufacturing process. Among the materials which have been recovered from the flotation circuit and marketed at times are mica and graphitic fines. Some cement kiln flue dusts have been retained and treated to recover potash. One plant formerly recovered 10 to 15 tons of solid carbon dioxide per day from the flue gas. Various waste rocks necessarily quarried in the selective mining of usable material are crushed and sold as aggregate for concrete.

When demand for cement was weak, some cement plants turned to the manufacture or processing of other materials for which they were equipped and favorably located to handle. These included crushed stone for agricultural use, road stone or flux; fertilizers; and the custom crushing of other minerals or materials. Idle kilns were converted to the production of lime and occasionally to various other uses, such as sintering clays and shales to obtain lightweight aggregates; nodulization or agglomeration of iron ore for open hearth and blast furnaces; production of sponge iron; calcination of petroleum coke, dolomite, and limestone; and drying and calcining bauxite, manganese ore, and phosphate.

ALTERNATE MATERIALS

Cement is an essential constituent of concrete and there is no substitute for cement in this field. As the binder in concrete for engineering construction, such as architectural concrete, highway and airport pavement, residential construction, water and irrigation systems, and many other applications, portland cement has comparatively little competition. However, for many concrete uses the consumer has a choice of alternate materials (such as bituminous concrete for highways) or for using other materials in combination with concrete to lower his concrete requirements. The choice of principal structural material is governed by many factors such as cost, personal preference, and building codes and specifications.

Building tiles, bricks, and blocks can be made of sand and lime by radically improved methods in a steam autoclave, and if costs and physical characteristics are as advantageous as claimed, these materials may become a substitute for portland cement concrete blocks in some applications.

There are many substitute or alternate raw materials for cement manufacture, if they are ever needed. For example, wollastonite could be used as a cement raw material if proportioned properly with other raw materials, and muscovite schist or pretreated spent oil shale can substitute for clay. In Europe some cement is a byproduct of sulfuric acid manufacture from gypsum or anhydrite.

RESERVES

From a world standpoint, there is no problem concerning the abundance and adequacy of raw material and fuel resources for the manufacture of portland cement. There do exist, however, local shortages of suitable raw materials; in some instances it may be cheaper to pay freight charges than to attempt to manufacture the cement locally. Occasionally, local studies will reveal previously unrecognized sources of material that can be utilized with proper blending, mixing, or other treatment.

CONSERVATION PRACTICES IN PRODUCTION AND USES

Industrial waste products may be substituted, in part, for some raw materials. Blast-furnace slag may substitute for clay or shale in the raw mix. Residues from caustic soda production or waste from marble quarries may be used to supply calcium carbonate. Iron oxide may be

obtained from copper smelter residues or wastes from plants obtaining sulfuric acid from pyrite.

As previously mentioned, during burning operations, longer kilns, internal heat exchangers, and preheaters conserve fuel and flue dusts may be recirculated.

Portland-slag cements are made at some plants by grinding granulated blast-furnace slag with portland cement clinker as a means of increasing production without increasing kiln capacity.

Portland cement requirements in concrete is sometimes reduced from 10 to 35 percent by blending fly-ash, slag, spent oil shale, or one of many natural pozzolans such as volcanic tuff or diatomaceous earth with the cement before or during concrete manufacture.

SOURCES OF STATICAL INFORMATION

The Bureau of Mines maintains statistical coverage of cement production and shipments (by both producing district and destination). Raw material and energy requirements, transportation methods, mill values, and plant capacity are surveyed. The Bureau summarizes production statistics from all principal cement producers in the world and compiles U.S. import and export figures from Census Bureau records. Cement data are published monthly in Cement Mineral Industry Surveys and annually in the cement chapter of Minerals Yearbook, volume 1.

The Business and Defense Services Administration of the U.S. Department of Commerce maintains and publishes statistics on costs and consumption of concrete products and ingredients, including cement, in the construction industry.

PRODUCTION, CONSUMPTION AND TRADE

Booms in building result in increased demand for cement; curtailment in civilian construction during wars and business depressions results in rapid loss of market. Even a single program can have substantial impact on the industry. For example, the present huge interstate highway program has used concrete for either paving surface or soil cement or concrete somewhere in the base or sub-base in more than 70 percent of the mileage built through 1963.

World production of cement fluctuated around 300 million barrels per year during the 1920's, 1930's, and first half of the 1940's. From 1946 through 1958 production increased from 500 million to 1.5 billion barrels, and to 2.2 billion barrels in 1963, as more countries developed increased need for cement to enable industrial expansions.

Production of portland cement in the United States increased consistently until 1928 when 176 million barrels of cement was produced. It dropped to 64 million barrels in 1933 before starting to rise again. In 1942 production reached 184 million barrels, but in 1944 had decreased to 94 million barrels. The recovery was more rapid after World War II, and in 1947 production was again 187 million barrels, and has continued to rise consistently, reaching 353 million barrels in 1963.

Finished portland cement is a perishable commodity if exposed to moisture. Stocks of finished portland cement at the producing plants are usually about equal to 1 month's production. Although no figures are available to indicate how much stock is on hand at the customer's level, it is considered to be a very small amount.

As shown in table 1, foreign trade has never assumed much national importance in the U.S. cement industry. Most imported cements have been either used along certain sections of the east coast which are at some distance from the nearest plant in the United States, or they consist of special types which are used in such small quantities that domestic manufacturers find it impractical to manufacture and market them. After World War II, exports were greater than usual because of high demand from underdeveloped nations, but that market for U.S. cements declined owing to the increasing self-sufficiency of those nations and to the increased competition from the revived European cement industry. Manufacturing costs in some countries may be markedly higher than in the United States, but the cost of transporting U.S. cements makes locally produced cement cheaper on a delivered basis.

Imports from other countries into the United States are subject to duties as follows: Roman (natural), portland and other hydraulic cements and cement clinker (except from Communist countries, in which case the rate is 6 cents per 100 pounds), 2¼ cents per 100 pounds; white nonstaining cement, 3 cents per 100 pounds (8 cents for Communist countries).

TABLE 1.—*Summary of statistics of the cement industry* [1]

	1954–58 (average)	1959	1960	1961	1962	1963

[1] Includes Puerto Rico.
[2] Includes hydroplastic, plastic, and water proofed cements.
[3] Includes number of plants making air-entrained portland cement as follows: 1959, 119; 1960, 120; 1961, 120; 1962, 121; and 1963, 121.

TABLE 4.—*Prepared masonry cement shipments from mills in the United States*

Year	Active plants	Shipments		
		Thousand 280-pound barrels	Value (thousands)	Average value per barrel
1954–58 (average)	121	14,817	$53,801	$3.63
1959	134	16,174	61,155	3.78
1960	140	19,134	56,485	2.95
1961	143	19,275	55,737	2.89
1962	144	19,998	57,405	2.87
1963	143	20,997	59,599	2.84

TABLE 5.—*Natural, slag, and hydraulic-lime cement shipments from mills in the United States*

Year	Active plants	Shipments		Average value per barrel
		Thousand 376-pound barrels	Value (thousands)	
1955–58 (average)	5	795	$2,567	$3.23
1959	4	441	1,450	3.29
1960	4	548	1,949	3.56
1961	4	269	968	3.60
1962	4	402	1,611	4.01
1963	4	352	1,407	4.00

GOVERNMENT PROGRAMS

Although little direct action was taken by the Government regarding cement production during World War II, orders by the War Production Board stopping all nonessential public and private construction effectively curtailed cement production in most of the country.

The defense program of World War II, particularly in Texas and California, gave impetus to demand for cement in those States and in certain other areas throughout the United States. Construction of Army and Navy installations, large atomic plants, airfields, and the like required large quantities of cement and caused such dislocations in nearby cement trade channels as local shortages and rationing, and temporary unavailability of cement.

The Area Redevelopment Administration and the Farmers Home Administration, as part of their programs include local cement production facilities in their consideration of means to implement their areal improvement objectives.

The Federal Trade Commission monitors acquisitions and mergers within the industry to prevent lessening of competition or creation of monopolies within market areas or industry segments.

Under the regulations of the Anti-Dumping Act, the Treasury Department audits cement imports to insure that they are not sold below a reasonable price. The U.S. Army Corps of Engineers, Bureau of Reclamation, Geological Survey, Bureau of Standards, and Bureau of Mines all maintain programs on particular areas

of cognizance concerning quality testing of cement, and concrete, or inventory of raw materials.

PRICES AND COSTS

Cement price patterns are so complex that no simple portrayal is possible. Discounts for cash and large quantity, freight absorbtions, and bagging costs vary with the local markets. Local prices for 20 United States and 2 Canadian cities with current discounts and special charges are published monthly in Engineering News-Record. The Bureau of Mines publishes quarterly, only the f.o.b. mill value of cement in bulk.

When the American portland cement industry began in the late 19th century, cement was $3 per barrel, and after 80 years of price fluctuation to a low of 81 cents per barrel in 1909, the price was approximately $3.35 in 1960. Since 1960, overcapacity and concomitant competition has forced average value down to $3.20 in 1963.

The percentage increases in price for cement have lagged far behind competing building materials such as lumber. Since 1930, other building materials have increased five times in price but cement prices have increased only three times.

Cement prices reflect reduced costs due to operation of larger and more efficient equipment and greater output per man-hour. In addition, capital investment for new plants has declined from about $30 per barrel of installed annual capacity in 1946 to from $6 to $12 per barrel. This lower unit investment is due primarily to the trend toward larger capacity plants and production machinery.

However, the increasing use of local distribution terminals to hold or expand markets under present rigorous competition has partly offset savings in production plant investment. These distribution terminals cost $200,000 to $2 million each to build.

Labor costs have been reduced by use of higher capacity machinery combined with centralized controls with electronic or automatic equipment. One operator can now supervise production steps which formerly may have required several dozen production workers. X-ray spectrography has reduced personnel requirements in the analytical laboratory. The amount of labor required to manufacture a barrel of cement is estimated to range from 6 to 15 man-minutes depending upon size and degree of automation of the plant. If employment costs are estimated at $3.50 per hour then there is from 36 to 88 cents labor in producing a barrel of cement. In 1963, an estimated 26,000 persons were employed in cement plants and the quarries or mines serving them.

TAXES

Most of the ordinary cement raw materials are granted a percentage depletion of 5 percent. A few, for example fuller's earth, quartzite, metallurgical and chemical limestone, and diatomaceous earth, are granted the 15 percent rate.

TRANSPORTATION AND PACKING

Transportation cost restrains the volume of imports and exports, limits the market area of the individual plant, and plays a major role in governing the movement of cement within an area and from one area to another. The general effect of the so-called Basing Point Decision (*12*), which declared illegal any practice whereby cement companies would agree to quote certain prices for their products at designated pricing points, forbids collusive pricing but allows absorption of freight charges by individual firms acting independently to permit them to compete in the available market.

Specially designed equipment is used to handle cement in bulk. Originally, shipments of cement were in barrels to protect the product from exposure to moisture, but the barrel has not been used as a container for many years. In 1963, over 85 percent of the shipments of cement was in bulk and nearly all the rest in paper bags.

However, the traditional units of measure, 94-pound bags (1 cubic foot of portland cement) with four bags equal to one 376-pound barrel is still used in the United States. An exception is prepared masonry cement which is measured in 280-pound barrels.

Bulk transportation is by special automated trucks, railroad cars, ships, and barges which are self-unloading and eliminate costs of packing and containers. Cement firms operate 200 distribution centers including storage silos for bulk cement to service local markets and some large users, such as ready-mixed concrete companies, have similar storage facilities.

For the small proportion of cement still packaged, pneumatic handling, automatic baggers and palletizers, and spring conveyors have increased efficiency. Improved plastic-lined bags have reduced to a minimum losses due to sack breakage and moisture absorbtion.

RESEARCH

The Portland Cement Association, Chicago, Ill., conducts technical research, provides an information service, undertakes promotional and educational efforts (including safety work), and develops new or improved products and methods. The broad program of the Association is financed out of dues contributed by the majority of the cement manufacturers of the United States and all cement manufacturers in Canada.

Through the publication and application of its own research findings, its cooperation with other research and technical organizations, and the daily contact of its own engineering staff with the problems of the designer and builder, the Association functions as a clearing house for information on portland cement, the making of concrete, concrete design procedures and construction methods.

In 1950 the Association completed the first section of its new research and development laboratories at Skokie, Ill. Additional facilities were opened in 1958. These laboratories are the largest and most completely equipped laboratories in the world devoted exclusively to research and development in the uses of portland cement and concrete. In addition, field laboratories and experimental projects are maintained at other locations. The Association conducts many experimental programs including work on items such as shrinkage control, air-entrained concrete, the water-cement ratios of concretes, soil-cement, pressure grouting, tilt-up construction practices, prestressing methods and materials, precasting, and cement hydration.

Many individual companies maintain small experimental laboratories and a few have fairly large research establishments. One firm has been testing the Pyzel vertical fluidized reactor system for producing low-alkali cement.

Many private, commercial, and engineering college laboratories conduct tests and experiments, usually on the various phases of concrete manufacture and use rather than on cement as such.

The American Concrete Institute gathers, correlates, and disseminates information for the improvement of the design, construction, manufacture, use, and maintenance of concrete products and structures. Through its Technical Activities Committee and Standard Committee standard specifications, practice recommendations, and definitions are developed and promulgated.

The Bureau of Standards conducted an important international symposium on cement chemistry in 1960 (*8*). The Bureau of Reclamation tests cement and concrete mixtures for use in dam construction. The Bureau of Mines conducts studies on the use of concrete in mining supports, bulkheads, linings, and ground stabilization or sealing by grouting techniques, and also tests natural pozzolan raw materials.

OUTLOOK

The cement industry will continue to expand both in response to population growth and to growing need in highway and industrial and housing construction.

Cement requirements in 1975 may be estimated by projections based on several pro-syllogisms. These are actual past cement production, population growth, gross national product, and value of construction. Cement production (in million barrels) in 1975 by each method would be 500, and 646 respectively. These figures assume population will increase a 1.6 percent compounded annually, gross national product in constant dollars at 3.8 percent per year and construction value (constant dollars) at 4.8 percent annually during the projection period. Respective average annual increases since World War II (to 1963) have been 1.7, 3.6, and 4.8 percent. It is therefore estimated that cement production in 1975 will be more than 500 million barrels. Some cement experts feel that the high projection, 646 million barrels based on construction value in constant dollars is the most valid criterion, but cement production increases since World War II do not substantiate this estimate.

The continued development of new methods of using cement and concrete and improvements and new variations in the product constantly offer new opportunity for America's builders and new challenges for the imagination and ingenuity of our architects and engineers. Prestressed concrete, soil-cement paving, thin-shell cantilevered concrete roofs, sculptured and exposed aggregate panels, lightweight concrete, expansive cement, precasting, slip-form casting and factory-built modular units are all recent stimulants.

The high initial investment required in the industry hinders the formation of new firms. Present ownership patterns will continue, for the most part, and these established firms will develop most of the new capacity in the industry. As new capacity is completed, some older, obsolescent high-cost production plants will be deactivated.

Advances in technology such as increased thermal efficiency (or even new type kilns), more complete automation, and large, low unit-cost production machinery will continue to hold production costs in check and assist in maintaining or improving cement's competitive posture against other traditional building materials. The introduction of new synthetic panels is not expected to have much effect on cement requirements, but they will compete instead with lightweight non-load-bearing materials such as wallboard, plaster, wood, plywood, glass, thin-gauge metal, and stone veneers.

Reserves of raw materials, including fuels required for cement production, are adequate for many years. Particular quarries now providing material to some plants may be exhausted, but other sources are expected to replace them without undue hardship. In addition, many alternate raw materials that have never been used for cement manufacture in the United States, exist in quantity if ever needed.

PROBLEMS

The cement industry's major current problem is improving its cost-price ratio in the face of fierce intra-industry competition. This is important to permit development of new capital for investment in replacing obsolete, and installing new, production capacity that will be needed to supply projected cement needs of the country.

The apparent close approach to practical limits on the size of rotary kilns presents a challenge to develop new type kilns or other production equipment with increased efficiency and concomitantly lower costs.

The complete solution to the problem of weakness of concrete in tension still presents a challenge to research engineers, although prestressed concrete has made a giant step in this direction.

Statistics on cement market areas and on use patterns are not collected or disseminated in sufficiently refined detail to completely satisfy the needs of market analysts in this sensitive, high-volume market place. Finished cement is perishable and must be stored in enclosed silos of definite capacity so that production and shipments are closely tied to local short-term market projections.

The continued development of stable, serviceable concrete that will not develop either shrinkage cracks or require expansion joints remains a challenge.

Obsolete building codes, in some localities, preclude optimum use of new concrete types, products, and methods. Coordination of structure design and quality of construction workmanship is difficult. This causes wasteful overdesign as a defensive measure. Vertical integration of the industry permitting broader quality control over concrete manufacture and construction workmanship has been proposed as a means of overcoming this problem.

Even though more than 85 percent of the cement shipped is in bulk the majority of the American industry continues to use the antiquated system of barrels and bags in its accounting procedures instead of tons and pounds or the metric weight system. The fact that various countries use different weights for their standard bag and barrel makes world statistics difficult to correlate. Even in the United States, a bag or barrel of masonry cement does not equal the same measure of portland cement. The use of bags and barrels in the existing technical literature causes many persons to oppose a change in the weight system.

In some locations the production of a low alkali cement compatible with reactive aggregates remains a technical problem.

Dust is still considered a nuisance problem by neighbors of a few plants.

CESIUM

By Donald E. Eilertsen [1]

CESIUM, a metal highly reactive with air or water, was discovered in 1860 and came into small commercial use in 1926. The major commercial sources of cesium have been pollucite and a residue derived from processing lepidolite to lithium hydroxide. Currently imported pollucite from pegmatites is the commercial source of cesium; not much is known about cesium resources. Various methods have been developed to extract cesium from pollucite; the acid leaching process is commonly used.

Cesium has applications such as in photomultiplier tubes, infrared lamps, scintillation counters, and spectrophotometers. One of cesium's major problems is the lack of large-scale uses. Moderate increases in the consumption of cesium and its compounds are predicted for conventional applications. However, larger consumption of cesium could result if uses as a rocket propellant and in generation of electrical energy develop.

BACKGROUND

Cesium was discovered in 1860 and isolated in 1881, while pollucite was discovered in 1846 but was not postively identified until 1864. Cesium had practically no industrial use until 1926, but thereafter for a few years it was used to coat filaments in tungsten vacuum tubes. Pollucite was first mined in the United States in Oxford County, Maine, from 1926 to 1929. Prior to 1957, very small domestic supplies of cesium raw materials were available. In 1958, the American Potash & Chemical Corp. began recovering cesium compounds from residues of a Texas plant that extracted lithium hydroxide from imported lepidolite. The residue, known as ALKARB, was the major commercial source of cesium for a short time. Currently, imported pollucite is used as the commercial source of cesium.

SIZE AND GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

In recent years, six firms in the United States have extracted cesium commercially. They are American Potash & Chemical Corp., Trona, Calif.; Dow Chemical Co., Midland, Mich.; Penn Rare Metals (subsidiary of Kawecki Chemical Co.), Revere, Pa.; MSA Research Corp., Callery, Pa.; Rocky Mountain Research, Inc., Denver, Colo.; and U.S. Industrial Chemicals Co., Cincinnati, Ohio.

[1] Commodity specialist.

DEFINITION OF TERMS, GRADES, AND SPECIFICATIONS

Cesium (Cs) is soft, silver white, and the eighth lightest metallic element (*2*)[2]. It is the heaviest of the alkali metals, explodes violently when brought into contact with water, and ignites spontaneously, burning with a brilliant blue flame, when contacted with air (*5*). Some of its other properties are atomic number, 55; atomic weight, 132.91; density, 1.87 g/cm^3 at 20° C; melting point, 28.5° C; boiling point, 705° C; ionic radius, 169 A; and ionization potential, 3.87 volts.

Typical analyses of cesium metal and compounds follow (*5*):

Elements	Cesium metal, percent		Cesium compounds, percent
Cesium, minimum	99.5	99.9	99.9
Sodium, maximum	.11	.01	.01
Potassium, maximum	.01	.01	.005
Rubidium, maximum	.10	.01	.05
Lithium	[1]	[1]	[1]
Calcium, maximum	.10	.01	----------
Silica, maximum	.01	[2].005	----------
Iron and aluminum, maximum	.01	.001	.001
Calcium and barium, maximum	----------	----------	.01

[1] Not detected.
[2] Average.

[2] Italicized numbers in parentheses refer to items in the list of references at the end of this chapter.

ALKARB.—A dry product formerly made in San Antonio, Tex., from end liquor resulting from the extraction of lithium values from lepidolite. It consisted of mixed alkali carbonates usually containing about 2 percent cesium and 20 to 25 percent rubidium carbonates. Lithium operations in the United States no longer use lepidolite as a source of lithium.

TECHNOLOGY

Mineralogy, Geology, and Mining

Cesium and rubidium often occur together in nature. The earth's crust is estimated to contain 7 parts per million of cesium compared with 310 parts per million of rubidium.

Pollucite, a mineral resembling quartz, is well known for its high cesium content. The chemical formula of pollucite is essentially $H_2O \cdot 2Cs_2O \cdot 2Al_2O_3 \cdot 9SiO_2$, and on this basis it contains 40.1 percent cesium or 42.5 percent cesium oxide (Cs_2O). Lepidolite, carnallite, and beryl occasionally contain cesium. Field tests for cesium have been developed to help prospectors identify the element (*1*).

Cesium occurs in certain granites and granite pegmatites; granites have been estimated to contain an average of 60 parts per million of cesium.

Pollucite and lepidolite are recovered commercially from pegmatites. They are mined as a coproduct with other valuable pegmatite minerals, usually by open-pit techniques ranging from large mechanized operations to small ones employing mostly hand labor. Rich ore shoots have been extracted by underground methods. Hand-sorting methods are generally used to recover pollucite.

Metallurgy

Recovery From Pollucite

Cesium can be extracted from its mineral concentrate by various methods such as acid leaching, basic fusion followed by water leaching, and direct reduction of the mineral concentrate. The acid leaching process is commonly used, and any one of a number of acids may be utilized to prepare the concentrate for the recovery of cesium.

One method used to extract cesium from pollucite is briefly described as follows (*4*):

Ground pollucite concentrate is treated with hydrobromic acid and then filtered to remove silica. The soluble bromides of cesium, other alkali metals, and aluminum are treated by a modified solvent extraction process utilizing isopropyl alcohol to remove aluminum bromide. The cesium and other alkali metal bromides are then evaporated, water is removed, and the mixed alkali bromides are treated in an extractor, where liquid bromine is added. After this reaction, the mixture is filtered to remove the alkali metal bromides. The resultant cesium tribromide solution is evaporated. Bromine is liberated, and the high-purity cesium bromide formed is reduced with a reactive metal to high-purity cesium metal.

Recovery From Lepidolite Residues

Two extraction methods to recover cesium salts from lepidolite residues are described as follows (*3*):

The first step in the chlorostannate method involves dispersing carbon dioxide flue gas in the starting solution of mixed alkali carbonates to precipitate 70 percent of the contained potassium as potassium bicarbonate. The remaining alkali carbonates are converted to chlorides. The cesium is then precipitated by adding only enough stannic chloride initially to form insoluble cesium chlorostannate. The more soluble rubidium remains in solution and subsequently is precipitated by adding excess stannic chloride. The cesium chlorostannate precipitate is purified by dissolving it with hydrochloric acid, reducing it to the stannous state, and then reprecipitating pure cesium chlorostannate. Cesium chlorostannate may be decomposed to the chloride by pyrolysis, electrolysis, or reduction with iron.

The alternate ferrocyanide method is used if the ferrocyanide or carbonate forms are the desired cesium end products. Sodium zinc ferrocyanide is added to the mixed alkali carbonate solution to precipitate cesium zinc ferrocyanide. The cesium zinc ferrocyanide can be decomposed to mixed carbonate by heating in air. A water leach dissolves only the cesium carbonate from the roasted material, and the resulting cesium carbonate solution is evaporated to dryness.

Reduction of Compounds to Metal

Cesium metal has been prepared in many ways. One method is to reduce cesium carbonate by reacting it at red heat with a metal. This process yields high-purity cesium, oxides of the reductant utilized, and carbon. Alternate promising reduction methods include heating cesium hydroxide with aluminum or magnesium in a stream of hydrogen, reacting cesium chloride vapor with heated calcium carbide (or calcium metal) under vacuum, and vacuum reduction of cesium fluoride with magnesium. Cesium metal has been produced experimentally by electrolysis, but this method has not proved economically feasible to date.

Because cesium is highly reactive, the metal must be recovered under an inert oil in a suitable receiver.

USES

In recent years quantities of cesium have been consumed in research and development of ionic propellent engines and generation of thermoelectric power, both of which have attracted widespread attention particularly for spaceflight applications.

In the ion engine, vaporized cesium is diffused through a heated porous plate. The cesium atoms become positively charged ions, and an electric field accelerates the positive ions to a velocity of approximately 300,000 miles per hour. The high-velocity ions are exhausted through a nozzle to develop thrust.

Thermionic converters under development convert heat to electricity by the thermionic activity of cesium plasma. One thermionic generator using five cesium diodes and solar energy was reported capable of generating 100 watts of electrical power.

In addition to these large potential applications, moderate quantities of cesium are used in the manufacture of photomultiplier tubes, infrared lamps, scintillation counters, and spectrophotometers.

Cesium is the active agent in producing electricity from light.

During World War II, cesium was used in infrared lamps for invisible signaling; in sniperscopes and snooperscopes similar to devices now in use by some night watchmen, guards, and border patrols; and in the photocell in the nose of the "homing" projectiles to track, intercept, and destroy enemy planes in flight.

An atomic clock which has an accuracy of 5 seconds in 300 years is operated with cesium.

Cesium iodide and cesium bromide crystals are used in some scintillation counters because they emit electrons when exposed to nuclear radiation. Cesium bromide infrared spectrophotometers are available to measure semiconductor epitaxial film thickness.

Certain cesium salts have been used in the medical field as an antishock after administering arsenical drugs.

Cesium may be used as a scavenger of gases and other impurities in chemical processing and in both ferrous and nonferrous metallurgy. It is used as an absorbent to remove impurities at carbon dioxide purification plants and acts as a catalyst in various hydrogenation and polymerization processes.

Besides being used as a source of cesium and rubidium, ALKARB is used in glass, ceramic glazes, and porcelain enamels where the alkalies modify the chemical and physical properties of the product.

BYPRODUCTS AND ALTERNATE MATERIALS

Pollucite is usually mined as a byproduct of lepidolite or beryl, and its production is dependent upon profitable sale of those minerals. ALKARB was recovered as a byproduct of processing lepidolite for lithium. The quantities of cesium- and rubidium-bearing carbonates and liquors available depend upon lepidolite consumption for lithium production. Cesium is rarely used as a substitute for other alkali metals because of its relatively high price.

Germanium, tellurium, selenium, and their compounds are alternate infrared-sensitive materials. Rubidium, potassium, thorium, mercury, and uranium tetrafluoride are possible substitute ion fuels.

RESERVES

Information on the resources of cesium is meager, and that which is known has been developed mostly as a result of prospecting, exploring, and producing other minerals from pegmatites, particularly lithium minerals. The principal commercial source of cesium is pollucite.

Some pollucite was produced from mines in Oxford County, Maine, and from the Tin Mountain mine near Custer, S. Dak., during the 1920's. A resource of pollucite may still exist in these deposits.

The largest known deposits of pollucite are those in the lithium-bearing pegmatites at Bernic Lake, Manitoba, Canada, which tentatively have been estimated to contain 350,000 tons of pollucite containing 20 percent cesium and substantial rubidium.

Rough estimates indicate that deposits in the Bikita district of Southern Rhodesia contain 150,000 tons of pollucite while deposits in the Karibib area of South-West Africa contain 50,000 tons of pollucite.

Cesium occurs in a number of other minerals such as lepidolite and in brines and saline deposits, but information on these cesium resources is scant.

SOURCES OF STATISTICAL INFORMATION

The Bureau of Mines canvasses the domestic cesium industry annually for statistical data on cesium source materials and cesium metal and compounds. Much of this data is withheld from

publication to avoid disclosing company confidential statistics.

PRODUCTION, CONSUMPTION, AND TRADE

In 1962, 50 tons of pollucite was reported mined in South Dakota. The cesium industry imports its supplies of pollucite for consumption mostly from Southern Rhodesia. Some pollucite has come from Mozambique and Canada.

Considerably more pollucite was consumed to produce cesium metal and compounds in 1963 than in 1962, but the overall consumption of pollucite continued to be small. Cesium metal production in 1962 was reported at 159 pounds. Statistical data on cesium and its compounds for 1963 are withheld to avoid disclosing company confidential information.

Import data on cesium compounds have been available since September 1963. Preliminary figures for 1964 showed imports of 106 pounds of cesium chloride valued at $5,802, and 1,915 pounds of other cesium compounds valued at $59,821, all from United Kingdom and West Germany. No data on exports of cesium metal and compounds were available.

Pollucite is imported duty free. Cesium metal is dutiable at 17 percent ad valorem, while cesium chloride and other cesium compounds are dutiable at 12.5 and 10.5 percent, respectively.

STRATEGIC CONSIDERATIONS

The cesium industry in the United States is dependent on imports for its supply of pollucite.

No lepidolite is being processed to lithium in the United States at present; consequently, there is no ALKARB production.

Cesium is not on the list of materials for stockpiling in the national strategic and supplemental stockpiles.

PRICES

Prices quoted for 99+ percent cesium during 1963 and 1964 were $100 to $375 per pound.

TAXES

The domestic and foreign depletion allowances for cesium are each 15 percent.

TRANSPORTATION AND SAFETY MEASURES (*5*)

Major precautions should be taken in handling, transporting, and storing cesium metal, because cesium is very reactive with water and air. Cesium is available packed under argon or in vacuum in Pyrex glass vials or returnable stainless steel cylinders. The vials of cesium are wrapped in aluminum foil and packed with vermiculite (expanded mica) in metal cans for protection against shock and fire. Cylinders of cesium are hermetically sealed and firmly supported in wood boxes filled with vermiculite.

Cesium compounds are not as dangerous as the metal. Nevertheless, they should be handled carefully and transported in closed containers for protection against contamination, deterioration, attack on the skin and membranes by some salts, and possible fire hazards.

RESEARCH

Cesium has been studied intensely by the Government in recent years in connection with the development of the ion engine. Testing of the engine in orbital flight is planned for 1965.

Cesium also has been studied intensely for thermoelectrical power.

The Bureau of Mines research on cesium and rubidium in recent years has been concerned with the development of concentration methods for pollucite, extraction and separation of cesium and rubidium, purification of cesium and rubidium salts, and determination of some of the thermodynamic properties of certain cesium compounds.

OUTLOOK

Moderate increases in consumption of cesium and its compounds are predicted for conventional applications. Large consumption of cesium could result if uses as a rocket propellant and in generation of electrical energy develop.

A few new pollucite deposits will probably be discovered and worked in the next 5 to 10 years as a result of the growing interest in cesium, but the major supply of cesium in the United States will continue to come from hand-sorted pollucite from Southern Rhodesia, South-West Africa, and Canada. Use of pollucite flotation concentrate will come closer to reality.

Occasional price cuts of cesium metal and compounds may occur as a result of increased demand for these products and perhaps as a result of improving methods to produce these materials.

PROBLEMS

Numerous problems confront cesium, extending from discovery of deposits through extraction, refinement, and the development of uses.

Cesium occurrences are numerous, especially in pegmatites, brines, and saline deposits, but information is lacking on the nature and extent of cesium in specific deposits.

Hand-sorted pollucite is currently the commercial source of cesium. Some success has been achieved experimentally in upgrading pollucite from ores rich in pollucite, but a problem exists in developing methods to conentrate pollucite economically from low-grade ores.

Costly multistage techniques employed to extract cesium from hand-sorted pollucite are largely responsible for the high prices of cesium metal and compounds. Methods to extract cesium simply and cheaply from this material as well as from various grades of pollucite flotation concentrate, other minerals, brines, and saline deposits are needed.

The lack of information on the physical and chemical properties of cesium hinders the progress of applied research and the development of uses. Furthermore, the alloying characteristics of cesium, particularly the development of intermetallic compounds, have not been extensively investigated.

Special precautions must be taken in preparing, handling, packaging, storing, and transporting cesium metal as the element is extremely reactive. Cesium ignites spontaneously in air, and reacts explosively with water; mists containing cesium compounds are caustic. Consequently steps taken to handle cesium safely contribute to the high prices of cesium products.

CHROMIUM

By R. W. Holliday [1]

CHROMIUM, best known as decorative plating, is indispensable in a broad range of other industrial applications. It is the chief alloying constituent of stainless steel. Chromium compounds are important chemical materials, and the mineral, chromite, is a major refractory.

The United States imports virtually all of its chromite, the only commercial chromium mineral. Domestic production was small even from 1951 to 1961, when the Government purchased chromite at incentive prices for stockpiling.

In the last decade the metallurgical industry accounted for about 60 percent of the total domestic chromite consumption, the refractory industry consumed 28 percent, and the chemical industry 12 percent.

Turkey, Southern Rhodesia, and Republic of South Africa have been major sources of metallurgical ore imports to the United States. The U.S.S.R. resumed shipment of chromite to the United States in 1959, after several years' suspension, and has become an important source. In the past most refractory ores came from Cuba and the Philippines. However, the Philippines and the Republic of South Africa are now principal suppliers. The Republic of South Africa is by far the largest source of ores used by the chemical industry.

Stainless steel accounts for about 65 percent of the consumption by the metallurgical industry and other alloy steel for about 25 percent.

Chromite refractory products are used principally in furnace linings. Being chemically neutral, they are especially useful in areas such as the slag line of basic open-hearth furnaces to separate the basic magnesite brick bottoms from the acid silica brick sides.

Chromium chemicals are used as pigments, in surface treatment and corrosion control of metals, in leather tanning, and in numerous other applications. The principal chromite chemicals are derived from sodium bichromate.

World consumption of chromite is expected to increase as world industrialization progresses. Southern Africa eventually will become the source for most of the world supply of chromite as high-grade reserves in other areas become depleted.

Problems include the need for lower cost mining and concentrating procedures plus wider consumer acceptance of fines and concentrates. Improved ductility and impact resistance of the metal and its alloys are needed. Other problems relate to discovery and exploration of deposits, transportation, and the need for better statistical data on foreign resources and consumption.

BACKGROUND

First discovered in Siberia as a lead chromate about 1765 and isolated as a metal in 1797, chromium was used primarily in the manufacture of chemicals until the early years of this century. Chromite deposits were discovered in Maryland and Pennsylvania about 1827 and these were the major world source until the discovery of Turkish ores in 1848. Although production was small by present standards, the U.S. deposits provided a basis for establishing a domestic chromium chemicals industry which has become the world's largest. Unsuccessful attempts to manufacture chrome yellow in 1828 and 1833 were followed in 1845 by a successful plant which produced potassium bichromate for American textile mills and pigment manufacturers. This early product led to development of a broad range of new chromium chemicals and new uses. After 1900 chromium gained importance as a constituent of alloys and as a refractory.

Ferrochromium has been known since 1820

[1] Commodity specialist.

through the studies of Faraday and Stodarts, and also by the work of Berthier. About 1860, Baur found that ferrochromium was the best material for adding chromium to steel. Other experimental work was done by Fremy, Percy, and Mushet. In 1873, Bierman, of Hanover, announced that his firm was producing ferrochromium commercially. By 1886 there were several regular producers of ferrochromium. Production of ferrochromium in the electric furnace began in 1899, replacing the blast furnace for this use. According to Brennan (*2*),[2] in 1906, the Electro Metallurgical Co. (Union Carbide) began producing ferroalloys at Niagara Falls as an extension of its predecessor companies in Virginia and West Virginia. Frederick Mark Becket joined the Niagara Falls organization in its beginnings and his early work resulted in the silicon reduction methods employing silicon or silicides for the production of low-carbon alloys, particularly low-carbon ferrochromium. Variants of Becket's methods are still used for the bulk of the low-carbon ferrochromium produced today.

World production of chromite increased from an estimated 59,000 short tons in 1900 to 4 to 5 million tons per year in 1954–63. Although a deposit in Harford County, Md., was the major world source from about 1827 until discovery of Turkish ores in 1848, most subsequent production has come from the Eastern Hemisphere.

From about 1930 till the end of World War II, Cuba was the principal U.S. source of refractory chromite. Since then Philippine (Masinloc) ore has been the standard refractory chromite, although in the last decade a new type from the Transvaal in the Republic of South Africa has won acceptance by the refractories industry. This African ore is higher in chromium and iron, and lower in alumina and silica, than the Cuban and Philippine ores. Reserves are virtually unlimited.

Most of the chromite consumed by the metallurgical industry is first converted in the electric furnace to one of several chromium ferroalloys. Stainless steel containing 12 percent or more chromium comprises the largest single use in the United States. Some chromite is converted to chromium metal for addition to special alloys, and some chromite in the mineral form is added directly to steel.

Processing by the refractory industry essentially involves sizing, blending, and necessary forming and curing or firing. Most of the chromite used by the chemical industry is converted first to sodium dichromate by roasting (with soda ash), leaching, and chemical separation.

[2] Italicized numbers in parentheses refer to numbers in the list of references at the end of this chapter.

SIZE AND ORGANIZATION OF THE INDUSTRY

Some chromite was mined in the United States in every year between 1899 and 1962; none was mined in 1962 or 1963. The domestic industry can supply only an insignificant part of domestic requirements. Total imports to the United States in 1954–63 averaged about 1.6 million short tons annually.

Some domestic consumers mine and import chromite through foreign affiliates or subsidiaries. Others purchase chromite through U.S. importing firms. Major foreign producers and U.S. importers were listed in a 1962 publication (*3*).

Eight domestic companies, operating 14 plants, produced 300,000 tons of chromium ferroalloys in 1963. Two firms produced chromium metal. These products were consumed for the most part by the steel industry, but about 5 percent went into high-temperature and other alloys.

Eight companies, operating 14 plants, consumed 358,000 tons of chromite in the manufacure of refractory products. Four companies operating six plants produced 130,000 tons of chromium chemicals, sodium bichromate equivalent.

GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

The domestic chromite mining industry, inactive in 1962 and 1963, is in California, Montana, Oregon, and Alaska. Distribution of the domestic consuming industry is given in table 1.

Foreign chromite production is virtually all in the Eastern Hemisphere. Based on 1963 data major producers, in descending order, are the U.S.S.R., the Republic of South Africa, the Philippines, Turkey, Southern Rhodesia, Albania, Iran, and Yugoslavia.

A tabulation of ferrochromium producers (*12*) listed world productive capacity in 1961 at slightly more than 1 million tons of high- and low-carbon ferrochromium, and this was expected to increase to 1.25 million tons by 1965. Of the total, North and South America were credited with 43 percent; Europe, excluding the Communist nations, with 32 percent; the Far East with 11 percent; and Czechoslovakia, East Germany, the U.S.S.R., and Yugoslavia with 14 percent. A significant increase was listed for Africa by 1965 (from about 20,000 to more than 100,000 tons).

TABLE 1.—*Principal U.S. consumers of chromite and producers of chromium products*

Company	Plant	Products
METALLURGICAL		
Baltimore Works of the Armco Steel Corp. (formerly Rustless Iron & Steel Co.).	Baltimore, Md	Stainless steel and iron.
Chromium Mining and Smelting Corp [1]	Riverdale, Ill	Exothermic high- and low-carbon ferrochromium; exothermic silicon-chromium alloy.
Union Carbide Corp., Metals Division	Niagara Falls, N.Y. Alloy, W. Va. Marietta, Ohio	Low- and high-carbon ferrochromium briquets; chromium metal; ferrochromium-silicon alloys; exothermic ferrochromium; exothermic silicon-chromium alloy.
Interlake Iron Corp	Beverly, Ohio	High- and low-carbon ferrochromium; ferrochromium-silicon.
Montana Ferro-Alloys Co., Inc., a subsidiary of Chromium Mining and Smelting Corp.	Woodstock, Tenn	High-carbon ferrochromium; ferrochromium-silicon.
Ohio Ferro-Alloys Corp	Brilliant, Ohio	Low- and high-carbon ferrochromium; ferrochromium-silicon; low- and high-carbon exothermic ferrochromium; exothermic ferrochromium-silicon.
Pittsburgh Metallurgical Co	Calvert City, Ky. Charleston, S.C. Niagara Falls, N.Y.	High-carbon ferrochromium; ferrochromium-silicon.
Shieldalloy Corp., Division of Metallurg, Inc.[1]	Newfield, N.J.	Chromium metal.
Tennessee Products & Chemical Corp.	Chattanooga and Rockwood, Tenn.	High- and low-carbon ferrochromium; chromium briquets; ferrochromium-silicon.
Vanadium Corp. of America	Niagara Falls, N.Y. Graham, W. Va. Vancoram, Ohio	Low- and high-carbon ferrochromium; chromium briquets; ferrochromium-silicon; chromium-bearing foundry alloys.
REFRACTORIES		
Basic Refractories, Inc.	Maple Grove, Ohio	Refractory shapes and mortars.
Eastern Stainless Steel	Baltimore, Md.	
General Refractories Co.	Baltimore, Md. Gary, Ind. Los Angeles, Calif.

DEFINITION OF TERMS, GRADES, AND SPECIFICATIONS

Chromite is the only commercial chromium mineral. Basically it is comprised of the oxides of chromium, iron, aluminum, and magnesium in varying quantities, all in solid solution. Traditionally, consumers in the United States have tended to classify the high-chromium chromite as metallurgical grade, the high-iron chromite as chemical grade, and the high-aluminum chromite as refractory grade. However, the different types are used interchangeably to some extent and the lines of distinction are not clearly defined. The national stockpile ore-purchase specifications, table 2, provide a reference that approximates commercial usage.

In practice, limited quantities of fines are used by both the metallurgical and the refractory industries. Acceptance of chromite as a refractory is based primarily on physical properties determined by performance tests, rather than on chemical composition.

In the past, most refractory ore has come from the Philippines and Cuba, but a type of chromite from South Africa has gained acceptance by the refractories industry. It approximates chemical-grade chromite in composition but is lower in silica, and tests have shown that it possesses the necessary refractory characteristics.

Ferrochromium is an alloy of chromium and iron used chiefly as a carrier for addition of chromium to iron or steel. Major classifications are based on carbon and silicon content as shown in table 3.

High-carbon ferrochromium is used to make medium and high-carbon steels of relatively low chromium content. Low-carbon ferrochromium is used in producing stainless, corrosion, and heat-resisting steels of low-carbon and high-chromium content. Foundry ferrochromiums are high in silicon. The low-chromium ferrochomium is known as charge grade because it is used in the initial charge in making stainless and other steels. Other chromium ferroalloys contain higher carbon or silicon, and some contain oxidizing agents, such as sodium nitrate, to react exothermically when added to molten iron or steel. Table 3 lists typical compositions.

TECHNOLOGY

Geology (*3*)

Chromite is used as a general name for all chromium-bearing spinels except the pure end members magnesiochromite ($MgCr_2O_4$) and ferrochromite ($FeCr_2O_4$) and is often expressed as (Mg, Fe) (Cr, Al, Fe)$_2O_4$. Chromite ranges in color from dark brown to black; it is usually opaque, but sometimes translucent. The streak is dark brown. Its luster is submetallic and its hardness 5.5 on Mohs' scale. The specific gravity ranges from 4.0 to 4.6 and the melting point from 1,545° C to 1,730° C. The fracture is uneven and the ore is brittle to tough.

Chromite occurs in peridotites and their derivative serpentines (pyroxenites and amphibolites) and in certain basic and ultrabasic stratified igneous rock complexes. The chromite deposits in peridotite and serpentine occur erratically as irregular or lenticular masses ranging in size from a few pounds upward to a million tons or more. The largest deposits occurring in stratified igneous complexes are uniform over large areas, and some exposures can be traced for tens of miles. Chromite also

Chemical [4]		44.0			5.0				

[1] Specification P-11-R1, June 4, 1956. This specification covers chromite ore suitable for use in the production of commercial ferrochromium and special chromium alloys. All chromite ore shall be lumpy and shall be hard, dense, nonfriable material of which not more than 25 percent shall pass a 1-inch sieve (ASTM Designation E 11). Chromite ore of a friable nature, regardless of an initially lumpy appearance, shall be rejected.

[2] Specification P-12-R3, Dec. 4, 1963. This specification covers refractory-grade chromite which is satisfactory for production of standard refractory brick. All refractory-grade chromite shall be hard, dense, nonfriable lump ore. Not more than 15 percent by weight of each lot shall pass a U.S. Standard Sieve No. 16 (ASTM designation E 11). Chromite ore of a friable nature, regardless of an initially lumpy appearance, shall be rejected. In addition to complying with the chemical and physical requirements of this specification, the chromite ore shall be from sources and of a type that is used, directly without chemical modification or processing, by at least 3-manufacturers of standard refractory chrome brick in the United States that consume at least 50 percent of the refractory chromite.

[3] Not specified but to be determined for each lot and reported.

[4] Specification P-65-R, Jan. 5, 1961. This specification covers chromite ore satisfactory for use in the manufacture of chromium chemicals. All chromite ore shall be of a friable nature.

TABLE 3.—*Composition of typical commercial grades of ferrochromium and chromium metal*

[In percentages of principal constituents][1]

Grade	Chromium	Silicon	Carbon	Sulfur	Other
Ferrochromium:					
High-carbon ferrochromium:					
Regular grade	66–70	1– 2	4–6		
Charge grade	50–56	4– 7	6–8	[2]0.03	
Charge grade	58–63	3– 6	5–8	[2].03	
Blocking and foundry grade	55–63	8–12	4–6	[2].03	
Silicomanganese grade	60–65	4– 6	4–6		Manganese 4–6.
Medium-carbon ferrochromium	60–65	[2] 3	2. 5–3		
Low-carbon ferrochromium:					
Regular grade	65–73	[2] 1. 00	0.025–2		
Vacuum grade 1	63–66	5– 7	.010–.025		
Vacuum grade 2	68–71	[2] 2. 00	.010–.025		
Nitrogen grade	67–71	0. 03– 1	.1		Nitrogen 0.75–6.
Ferrosilicon-chromium	50–54	28–32	[2]1.25		
Ferrochromium-silicon:					
34/46 grade	33–36	45–48	[2].05		
40/43 grade	39–41	42–45	[2].05		
55/24 grade	52–57	23–27	[2].05		
57/15 grade	55–59	13–17	[2].05		
60/10 grade	58–62	8–12	[2].05		
65/5 grade	63–67	3– 7	[2].05		
Chromium metal:					
High-carbon chromium metal	87–90		9–11		Iron 0.40.[2]
Low-carbon chromium metal	[3] 97	[2] 1	[2].1–5		Iron 1.20.[2]

occurs in detrital deposits formed by the weathering of peridotite and serpentine.

Mining

Chromite ores are mined by conventional methods adapted to the peculiarities of individual deposits. Opencut mining varies with the thickness of overburden, the size of deposit, and the mechanical equipment available. Underground methods are dictated by such factors as width and depth of the vein, characteristics of the wall rock, and available equipment. Narrow, high-grade veins may be extracted by resue methods. Flat-lying beds involve scraping for underground transport of the broken rock. Timbering, pillars, cribbing, or backfill may be used for ground support. Access may be through winze, adit, or shaft. With growing acceptance of fines and concentrates by consumers, a continuing trend to less selective mining methods can be expected.

Ore Beneficiation

The traditional use of lumpy ores for metallurgical and refractory applications largely eliminated any beneficiation, other than hand sorting and screening, until recent years. However, improvements in metallurgical practice are bringing greater acceptance of fines and concentrates by consumers, and depletion of ore deposits in some areas has prompted efforts to improve recovery.

Most concentration of chromite involves gravity methods such as jigs, tables, or spirals. Jigs are limited to larger particle sizes, and tables, though probably most efficient, are more costly than spirals. Grinding is necessary to liberate the chromite from gangue minerals, and this generates slimes which usually are rejected because of the cost of further treatment. Chromite ores can also be concentrated by flotation, by use of magnetic or electrostatic devices, and by use of a heavy medium.

Upgrading by physical methods is limited by the chromic oxide (Cr_2O_3) content of the chromite mineral; iron and other molecular constituents of the mineral can be removed only by chemical or pyrometallurgical procedures.

Processing

Chromium can be added directly to iron or steel as ore, but usually it is added as one of the chromium ferroalloys. Chromium metal is used to form alloys with metals other than iron or steel and in some special alloys (*3*, *16*, *19*).

High-carbon ferrochromium is produced by carbon reduction of chromite, usually in a three-phase submerged-arc electric furnace. Carbon and silicon content of the alloy are controlled by the use of flux, by blending of ores, and by changes of the operating temperature.

Medium-carbon ferrochromium is produced from high-carbon ferrochromium, usually by refining in an open-arc furnace with chromite or by blowing with oxygen in a Bessemer converter. Chromite, lime, silicon, and fluorspar are added to the molten high-carbon ferrochromium in the first of these methods. This is the preferred method in the United States.

Low-carbon ferrochromium is made by a two-stage silicon-reduction process. There are three principal variations, known as the basic process, the duplex process, and the ore fusion process.

In the basic process, ferrochromium silicon, produced as a first stage, is crushed, mixed with ore, lime, and fluorspar, and refined in an open-arc furnace to reduce the silicon. (The ferrochromium silicon is made either by direct smelting of ore, quartz, and coke or by smelting high-carbon ferrochromium with quartz and coke.)

The duplex process is similar but involves the use of an oxidizing agent such as sodium nitrate to induce an exothermic reaction. In the ore fusion process, a molten mixture of ore and lime is reacted with ferrochromium silicon and refined.

A number of special chromium ferroalloys are produced by modified charge and melting procedures. These include exothermic, high-silicon, and nitrogen or manganese-containing alloys.

Chromium metal is produced commercially in the United States by two methods. Three-fourths of the domestic output is obtained by electrolysis from a chromium-alum solution deriving its chromium from high-carbon ferrochromium. This process, developed by the Bureau of Mines (*13*), was first used commercially in 1954. Various other electrolytes also have been used, including chromic acid which is used for producing decorative chrome plating. An aluminothermic process is the second commercial method currently used in the United States. An exothermic reaction between chromic oxide and metallic aluminum powder in refractory-lined containers yields chromium metal of a quality that can be controlled by use of purified raw materials and variations in the production method. Other reductants such as silicon, carbon, calcium, sodium, and hydrogen also have been used. Ultrapure, ductile chromium has been produced experimentally by various methods. A Bureau of Mines method involves hydrogen treatment of high-purity electrolytic chromium (*1*, *4–5*, *7*).

Chromite refractories utilize raw ore alone or in combination with other materials, principally magnesia. They are marketed as bricks or shapes either fired or chemically bonded, as moistened or dry aggregates which can be poured or rammed into place, and as mortars and cements. Processing consists essentially of blending, crushing and grinding, screening and proportioning of grain sizes, mixing and tempering, molding, drying, and in some instances firing (*19*). Although refractory-grade ore traditionally has come from Cuba and the Philippines, a more recent development has been the use of ore from South Africa, utilizing sufficient high-purity magnesia to counteract the adverse affects of silica and iron oxides.

Most chromium chemicals are derived from sodium bichromate. Although various ores have been used in its production, the domestic chemical industry has largely standardized on Transvaal grade B friable chromite. This ore contains about 44 percent Cr_2O_3 and is low in silica which is considered the most objectionable impurity because it increases the consumption of alkali and lowers the fusion temperature, causing difficulties in roasting.

Manufacture of sodium bichromate involves roasting a mixture of finely ground chromite, soda ash, and lime; cooling, water leaching, and filtering; evaporation to a concentration of 40 to 45 percent sodium chromate (Na_2CrO_4); and treatment, usually with sulfuric acid, to convert the sodium chromate to sodium bichromate ($Na_2Cr_2O_7$). Concentration then is accomplished by evaporation (*6*, *18*).

USES

In the last decade (1954–63) the metallurgical industry accounted for 59.8 percent of total domestic chromite consumption (gross weight), the refractory industry accounted for 28.4 percent, and the chemical industry consumed 11.8 percent.

As noted earlier, most chromite consumed by the metallurgical industry is converted to ferroalloys and then consumed in the manufacture of stainless, high-speed, and other alloy steels. The consumption, by end uses, of ferroalloys and metal in 1963 is shown in table 4.

In quantities up to about 0.5 percent, chromium refines the grain and reduces segregation in alloy steels. From about 0.5 percent to 1.5 percent, chromium increases hardenability, inhibits graphitization at elevated temperatures,

and increases toughness. In quantities from 2 to 6 percent, chromium imparts high hardness and some corrosion resistance (*3*).

Outstanding resistance to corrosion and oxidation is imparted by additions of 12 percent or more chromium and it therefore is an essential constituent of stainless steels. More than half of the domestic stainless production is of the chromium-nickel and chromium-nickel-manganese (austenitic) type with chromium content ranging between 16 and 26 percent. Chromium appears in a wide variety of other alloy steels ranging in chromium content from less than 1 percent to as high as 35 percent.

In cast iron, chromium improves heat and wear resistance.

Many of the "superalloys" combine chromium with one or more metals, especially iron, nickel, cobalt, molybdenum, tungsten, or columbium. They find use in aircraft and space applications, atomic energy applications, and in the chemical, food processing, oil-refining, and steel industries.

Nickel-base chromium alloys embody resistance to heat and corrosion. They are used in thermocouples, jet engines and turbine blades, furnace equipment, heating elements, and handling equipment for hot or corrosive chemicals.

Cobalt-base chromium alloys are used where there is a need for hardness and corrosion resistance, oxidation resistance, and strength at elevated temperatures. They are used as metal-cutting tools, hard-facing materials, permanent magnets, and gas turbine blades.

Small quantities of chromium are also used in aluminum, copper, and titanium-base alloys.

Chromium metal is used in alloys where impurities are objectionable. It is also used in powder metallurgy and in the production of chromium carbide, used in some hard-facing and abrasion-resistant applications.

Chromite refractories are used in metallurgical and glassmaking furnaces and in limekilns. Because of their chemically neutral character, a major use is at the slag line of basic open-hearth furnaces to separate the basic magnesite brick bottom from the acid silica brick side.

The largest consumption of chromium chemicals is in the manufacture of pigments, and in leather tanning, textile processing and electroplating; but many other uses are important (*18*). Chromium chemicals are essential in the graphic arts. They are employed in fungicides and in a wide variety of chemical processes as catalysts, oxidants, etc.

Chrome plating is done from an electrolyte consisting of an aqueous solution of chromic acid. Chromate film coatings, anodizing of aluminum, and surface diffusion or chromizing are also important methods for protecting metals against corrosion.

TABLE 4.—*Consumption of chromium ferroalloys and chromium metal in the United States in 1963, by major end uses*

[Short tons, gross weight]

	Low-carbon ferro-chromium	High-carbon ferro-chromium	Ferro-chromium silicon	Exothermic ferro-chromium silicon	Chromium briquets	Other [1]	Total
Stainless steels	96,529	55,047	60,754	3	527	93	212,953
High-speed steels	564	1,012	39	----------	----------	17	1,632

Other nonferrous alloys [3]	426	1,372	----------	----------	16	695	2,509
Total (gross weight)	119,251	103,134	68,508	4,124	1,260	13,595	309,872
Chromium content	82,151	66,178	28,870	1,695	700	7,221	186,815

[1] Includes exothermic high-and low-carbon ferrochromium, chromium metal, and other chromium alloys.

[2] Includes quantities believed used in producing high-speed and other tool steels and stainless steels because some firms failed to specify individual uses.

[3] Includes cutting and wear-resistant alloys, hard-facing alloys, welding rods, electrical-resistance alloys, and other nonferrous alloys.

BYPRODUCTS AND COPRODUCT RELATIONSHIPS

Large potential chromium resources exist in laterite deposits in Cuba, the Philippines and elsewhere. However, no commercial process has been developed for extracting the chromium. The Nicaro plant in Oriente Province, Cuba, was designed to extract only nickel from these ores, rejecting iron, chromium, and some cobalt.

ALTERNATE MATERIALS

Alloys, plastics, and various composite materials offer a wide range of possible substitutes for chromium-bearing alloys. To some extent alumium trim can be used in place of chrome-plated trim. Chromizing or other surface treatment permits the use of chromium-surfaced steel as a substitute for more expensive stainless steel. A large-scale research effort over the last 10 to 15 years has been directed toward development of oxidation-resistant coatings for molybdenum, tungsten, and other high-melting-point metals. This research will undoubtedly influence the future use of chromium-bearing superalloys.

Magnesite can be substituted for part of the chromite used in the manufacture of some refractory products.

SECONDARY SOURCES AND RECOVERY

Stainless-steel scrap is the major source of secondary chromium. In 1963, the domestic gross weight consumption of stainless-steel scrap by the steel industry was 719,000 short tons, compared with stainless-steel production of 1 million tons. Other alloy steels and chromium-bearing special alloys also provide secondary chromium. These materials usually are remelted with no attempt to separate chromium from the other alloy constituents. However, at least one firm in the United States is recovering chromium (and other elements) in the form of salts. Certain of the superalloys reportedly are shipped to West Germany for recovery of constituent elements. Slags produced during the melting of various steels contain up to about 12 percent chromium that is not recovered.

RESERVES AND RESOURCES

World reserves and potential resources are estimated to total 2,660 million long tons, distributed as shown in table 5. World production in 1963 was less than 5 million tons. However, a great preponderance of the world resource is in only two nations; 2,000 million tons are in the Republic of South Africa and 600 million tons are in Southern Rhodesia. A second consideration is that about 84 percent of the total is high-iron, 16 percent high-chromium, and only 0.06 percent high-aluminum material.

U.S. chromite ores that are commercial by present standards are insignificant in relation to U.S. requirements. More than 90 percent of the domestic chromite resource is in low-grade, high-iron deposits, with by far the largest occurrence in the Stillwater complex, a layered igneous mass exposed over 30 miles in Stillwater and Sweetgrass Counties, Mont. The overall resource in this deposit is estimated at about 14 million long tons of ore ranging from 15 to 30 percent Cr_2O_3. Physical concentration of the Stillwater ore is limited because the iron is chemically combined as part of the chromite mineral. Operations at one property, during 1943, produced a concentrate averaging 38.8 percent Cr_2O_3 with a chromium-iron ratio of 1.44:1.

Other low-grade deposits of significant size are in the John Day district in Grant County, Oreg., in beach sands along the Oregon coast, and in Eldorado County, Calif. Small scattered deposits of higher grade chromite are known in several other counties of California, in Oregon, and in Alaska. Occurrences also are known in Idaho, Maryland, North Carolina, Pennsylvania, Texas, Washington, and Wyoming. Locations of chromite deposits in the United States and descriptions of domestic and foreign deposits have been published (*3*, *17*).

The largest chromite resource in Canada is in eastern Manitoba, in the Bird River igneous complex, which is similar to the Stillwater complex of Montana. The reserve is conservatively estimated at 9 million tons (to a depth of 660 feet) over a length of 6 miles. The chromite is even higher in iron than the Stillwater and yields lower grade concentrates.

Three chromite-producing areas in eastern Cuba have reserves totaling some 1.25 to 1.5 million tons of shipping-grade ore. The Mayari district yields metallurgical ore. The Camagüey and Moa-Baracoa districts produce refractory ore. A large potential also exists in Cuban laterites and serpentines, which are estimated to comprise some 3,000 million tons of material containing 1 to 4 percent chromium. However, no commercial extractive procedure has yet been developed. Chromite resources of Brazil have been estimated at a few hundred thousand tons, principally of milling-grade ores. Limited production has come from scattered deposits in Guatemala, but the known reserve is small.

The Republic of South Africa has a total chromite resource estimated at not less than 2

billion tons in the Bushveld complex in the Transvaal Province. Most of the material is friable and has a Cr_2O_3 content of 40 percent or more and a chromium-iron ratio or about 1.5 to 1. In Southern Rhodesia the reserves of the Great Dyke have been estimated to total 540 million tons, about one-third high-chromium and two-thirds high-iron, to a vertical depth of 500 feet on outcropping layers. Eluvial ores found adjacent to the Great Dyke may contain 60 million tons of concentrate. The total resource may be several thousand million tons. Other Rhodesian sources are the Selukwe, Mashaba, and Belingwe districts with a reserve estimated at some 8 million tons of high-alumina and high-iron ores.

Turkey long has been a major source of high-grade metallurgical chromite, but no definitive estimate of the total resource is possible. Geological inference suggests the probable existence of 10 million tons of shipping-grade ores and concentrates.

The Philippines have been the principal world source of high-alumina, refractory-type chromite for many years. The Coto ore body, northwest of Manila, is the largest deposit of this ore in the free world. The Acoje mine in Zambales Province, 10 miles north of the Coto deposit, has measured and indicated reserves of high-chromium ore exceeding 2 million tons. Other chromite deposits are distributed widely throughout the archipelago: Total reserves of refractory ore exceed 6 million tons; reserves of metallurgical ore in addition to the 2 million tons at Acoje are uncertain but probably not large.

Albania and Yugoslavia have produced metallurgical chromite consistently over the years from deposits along their common border, and reserves are estimated at about 500,000 tons for each country.

Little recent information is available concerning chromite reserves in the U.S.S.R., although the scale and high quality of recent exports imply a large reserve.

Chromite also occurs in Cyprus, Egypt, Finland, Greece, India, Iran, Japan, the Malagasy Republic, New Caledonia, Pakistan, Sierra Leone, and other countries.

TABLE 5.—*Estimated reserves and potential resources of chromite ore, by type and country* [1]

World total	2,661,000	16	426,000	84	2,220,000	.06	15,200

[1] The figures for reserves and resources are intended primarily to indicate the relative importance of the countries, based on available information; upon further exploration and development some figures may be increased several times.

[2] Cr_2O_3, 45 percent or more; chromium-iron ratio, 2 to 1 or more; used mostly in metallurgy.

[3] Cr_2O_3, 40 percent or more; chromium-iron ratio, less than 2 to 1; used mostly as chemical ores.

[4] Al_2O_3, 20 percent or more; mostly used in refractories.

Source: Reference (5).

CONSERVATION PRACTICES

Growing acceptance of fines and concentrates by consumers has tended to promote utilization of lower grade ores and increased reserves proportionately. Reworking of waste piles has proven feasible in some instances.

Chromium ferralloy producers recover chromium from slag, and chemical processors rework residues and waste electroplating solutions. Chromium-bearing scrap alloys comprise part of the chromium added in new production of alloys.

SOURCES OF STATISTICAL INFORMATION

Domestic production, shipments, consumption, and stocks of chromite ore and concentrate; production, shipments, consumption, and stocks of chromium ferroalloys and chromium metal; and production and stocks of chromium chemicals (sodium bichromate equivalent) are compiled and published monthly by the Bureau of Mines. Chromium ferroalloys consumed in making steel and the quantity of chrome-bearing steels produced are compiled and published by the American Iron & Steel Institute.

Data on foreign exports and imports are published in the "Statistical Summary of the Mineral Industry, Overseas Geological Surveys" (London), in the "Statistical Yearbook of the United Nations" (New York), and in monthly and annual publications of various countries.

These data are adequate to meet most needs of government and industry, except that additional information on chromite reserves of the world by grades and data on present and projected consumption and uses in foreign countries are needed for estimating the quantity that will be available to the United States.

Export and import data on chromite and chromium products and the production of chromium chemicals are compiled by the Bureau of the Census, U.S. Department of Commerce. Under revised tariff schedules no attempt is made to distinguish between metallurgical-grade, chemical-grade, and refractory-grade chromite. The U.S. Tariff Commission's "Tariff Schedules of the United States, Annotated, 1963," effective September 1963, listed the following classifications for chromium ore imports:

601.1520 ..... Having a chromium content equivalent to not more than 40 percent chromic oxide (Cr_2O_3).

601.1540 ..... Having a chromium content equivalent to more than 40 percent but less than 46 percent chromic oxide (Cr_2O_3).

601.1560 ..... Having a chromium content equivalent to 46 percent or more chromic oxide (Cr_2O_3).

PRODUCTION, CONSUMPTION, AND TRADE

Since 1916, the United States has produced chromite mainly during emergency periods and in 1951–61, when the Government purchased chromite at incentive prices for stockpiling. Annual world production by countries from 1900 to 1958 was published in the Bureau of Mines Minerals Yearbook for 1958; data for succeeding years have appeared in annual editions of the Minerals Yearbook. Salient data for 1963 are given in table 6.

Data on world consumption of chromite ore are incomplete, but an approximation can be derived from estimates of world chromite production together with a relationship to world steel production. World chromite production in 1963 was estimated at 4,475,000 short tons and world production of steel ingots and castings at 425,310,000 short tons, averaging 21.0 pounds of chromite per ton of steel.

On this basis, 1963 consumption of chromite is estimated at 930,000 short tons in the U.S.S.R., 365,000 tons each in West Germany and Japan, 265,000 tons in the United Kingdom, and 205,000 in France. Consumption in the United States was higher than the 21.0-pound average, and consumption in other countries presumably was slightly lower.

In the United States, consumption of all types of chromite in 1963 was equivalent to about 26 pounds per ton of steel. This is a derived figure relating to end use consumption and was obtained by adding the computed ore equivalent of ferroalloys and metal consumed to ore consumed by the refractories and chemical industries.

TABLE 6.—*Salient chromite statistics*

[Thousand short tons and thousand dollars]

	1954–58 (average)	1959	1960	1961	1962	1963
United States:

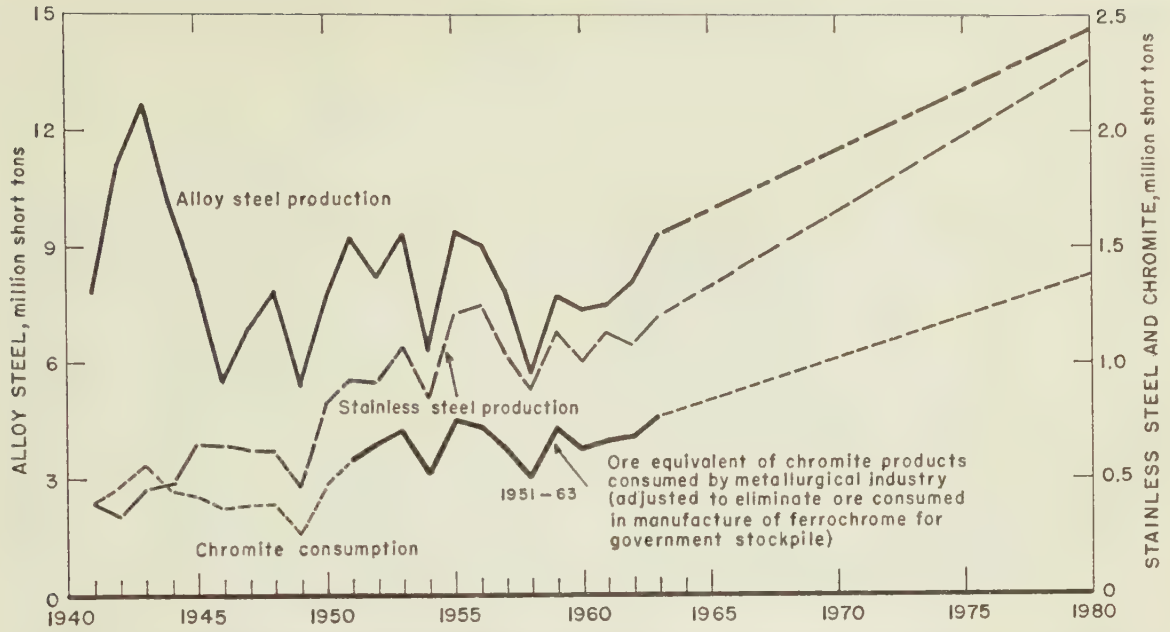

FIGURE 1.—Stainless and Other Alloy Steel Production and Chromite Consumption for Metallurgical Uses.

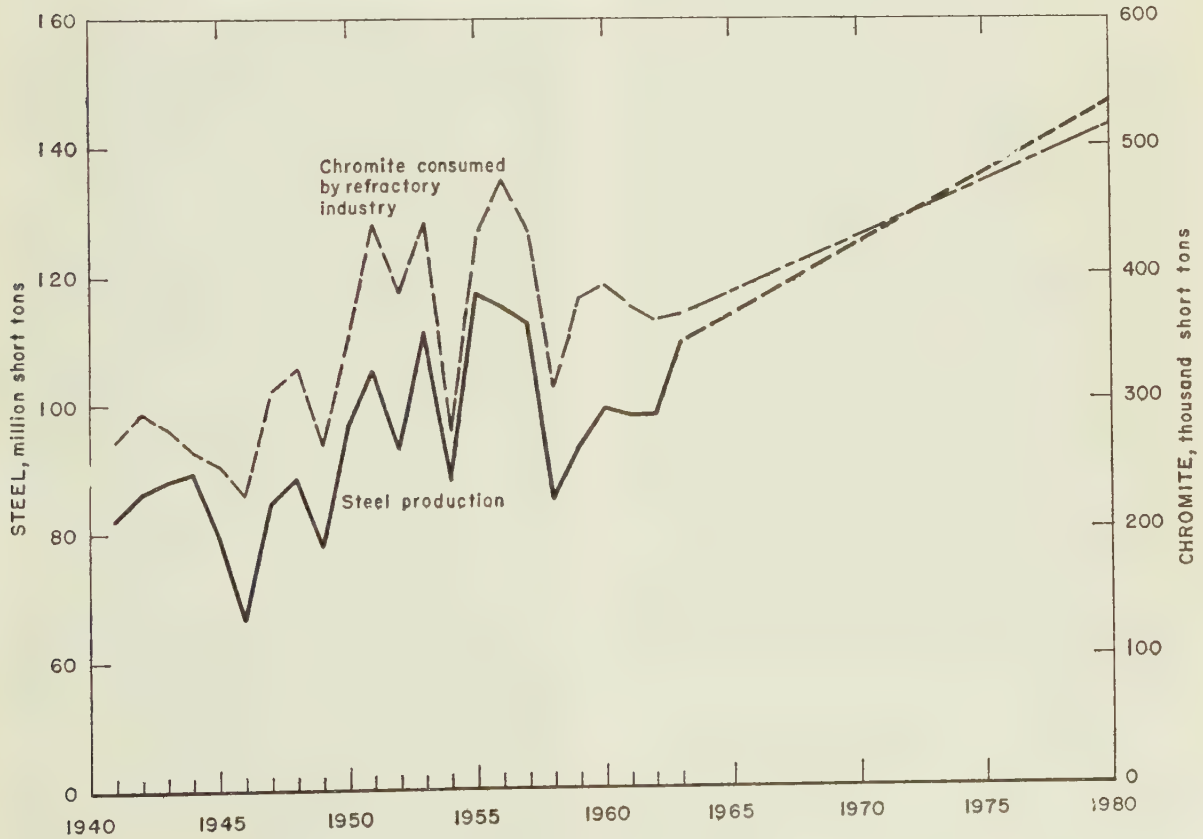

FIGURE 2.—U.S. Steel Production and Chromite Consumption for Refractory Uses.

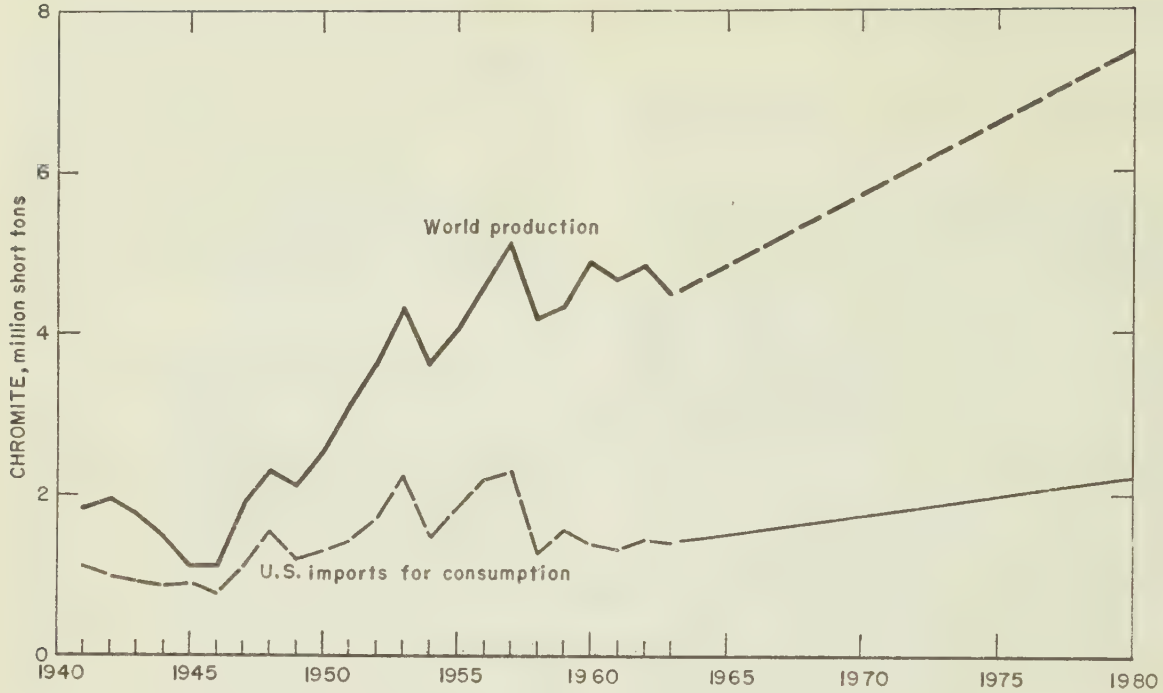

FIGURE 3.—World Production of Chromite and Imports to the United States.

Except for the U.S.S.R., industrial countries depend mainly on imports of chromite. In 1963, the world's new chromite supply came from the U.S.S.R. (30 percent), the Republic of South Africa (20 percent), Southern Rhodesia (9 percent), Albania (7 percent), and 13 other nations which produced the remaining 13 percent. Chromite imports comprised 100 percent of the new supply to the United States in 1962 and 1963 and virtually all except government stockpile purchases for the last decade.

In the 10-year period, 1954–63, imports from South Africa (30.4 percent), the Philippines (25.4 percent), Southern Rhodesia (19.9 percent), and Turkey (16.7 percent) comprised 92.4 percent of total U.S. imports. Imports from the U.S.S.R., after several years' suspension, were resumed in 1959 and comprised 14 percent of the total in 1963. No imports were received from Cuba in 1962 or 1963.

The United States has no import duty on chromite ores and concentrates. The Tariff Schedules of the United States, Annotated, 1963, effective September 1963, list duties as shown in table 7.

STRATEGIC CONSIDERATIONS

The United States is dependent on foreign sources for virtually all of its chromite. In 1956, the year of record domestic production, only 207,000 tons was produced and much of this was low in grade—purchased at incentive prices under the Government stockpiling program. Nevertheless, the resource conceivably could supply 5 to 10 percent of the Nation's needs under sufficiently critical emergency conditions.

The long sea lanes between the United States and its major sources in the Philippines, Turkey, the Republic of South Africa, Southern Rhodesia, and in recent years the U.S.S.R., present serious transportation problems during war. Rail transportation from mines and mills in the Western United States to processing plants in the East is costly and could be in short supply during an emergency. However, the Western United States is not a major source of supply. More important are the limited facilities for moving chromite from mine to port, and limited port loading facilities, in some of the major producing countries.

In Turkey, much of the high-grade metallurgical ore is hauled from mine to port by motortruck, and in past shortages of tires and spare parts have curtailed shipment. In South Africa, according to Greathead (*6*):

> The Eastern Belt is poorly served by only two rail-loading points, Burgersfort and Steelpoort, 11 miles apart by road, and mines more than 30 miles from them have not been worked to any extent. The distances from these railheads to the nearest port Lourenço Marques, are 336 and 351 miles, respectively.

TABLE 7.—*Rates of duty on chromium imports to the United States*

[Duty is assessed per pound]

Item	Article	Rates of duty	
		Free world [1]	Communist areas [2]
420.08	Potassium chromate and dichromate	2.25 cents per pound	2.25 cents per pound.
420.98	Sodium chromate and dichromate	1.75 cents per pound	1.75 cents per pound.
422.92	Chromium carbide	12.5 percent ad valorem	25 percent ad valorem.
473.10	Chrome green	10 percent ad valorem	Do.
473.12	Chrome yellow	do	Do.
473.14	Chrome oxide, green	do	Do.
473.16	Hydrated chromium oxide green	do	Do.
473.19	Strontium chromate	do	Do.
531.21	Chrome bricks	25 percent ad valorem	Do.
601.15	Chrome ore	Free	Free.
607.30	Ferrochromium not containing over 3 percent by weight of carbon.	8.5 percent ad valorem	30 percent ad valorem.
607.31	Ferrochromium containing over 3 percent by weight of carbon.	0.625 cent per pound on chromium content.	2.5 cents per pound on chromium content.
607.55	Ferrosilicon chromium	10 percent ad valorem	25 percent ad valorem.
632.18	Chromium metal	10.5 percent ad valorem	30 percent ad valorem.

[1] Duties apply to imports from countries other than U.S.S.R. and other designated communist areas.
[2] Duties apply to imports from U.S.S.R. and other designated Communist areas.

Rail facilities in the Western Belt are far better; although the distances to Lourenço Marques range from 380 to 490 miles. The road distances to the railheads from the present working mines vary from 2 to 18 miles.

In 1960 the Rhodesian industry and the railway system reportedly were geared to produce and export well over 1 million tons per year. However, the mines are more than 500 miles from either the Lourenço Marques or the Beira seaports, both in Mozambique.

U.S. Government stockpiles on June 30, 1964, totaled 8.0 million short dry tons, of which 5.5 million was metallurgical-grade chromite, 1.3 million chemical-grade chromite, and 1.2 million tons was refractory-grade chromite. Some of the material included in the above totals had been converted to ferrochromium or other products.

Chromite-consuming plants in the United States are dispersed so that they do not constitute an unusual protection problem.

GOVERNMENT PROGRAMS

Government policy was an important factor in domestic production between 1951 and 1961, when virtually the entire output was purchased at incentive prices under the Defense Production Act of 1950. Foreign chromite ores, chromium ferroalloys, and metal have been acquired through the exchange of surplus agricultural products.

To encourage exploration of domestic chromite deposits, the Office of Minerals Exploration offered assistance to private industry in the amount of 50 percent of the approved estimated cost. The moneys were to be repaid from production. This program was initiated in 1959 and was still in effect in 1963.

PRICES

Prices are determined by negotiation and no fixed standard applies either to base prices, premiums, or penalties. Sales of refractory ores are based on known refractory characteristics of ore from a specific source. Sales of metallurgical and chemical ores are based on chromic oxide content, impurity constituents, and the lumpy or friable nature of the ore. Lumpy ore with a 3 to 1 chromium-iron ratio is desired for most metallurgical uses. Friable ore is preferred for chemical use, and low silica content is desirable in all uses.

Average annual prices have ranged from about $10 per long ton (eastern seaboard) in 1921 to about $56 in 1957.

Published prices in 1963 were listed for the most part as nominal. Although some as low as $16 were rumored, these undoubtedly applied to fines or other less desirable materials. Prices for standard grades of metallurgical ore, in the United States, probably were in the range of $24 to $26 throughout most of 1963.

Chromium ferroalloys are sold in the United States by the pound of contained chromium and the prices vary according to composition and quantity. Prices quoted by E&MJ Metal and Mineral Markets at the end of 1963 for ferro-

chromium in carload lots f.o.b. shipping point follow:

	Cents per pound
High carbon 67 to 71 percent Cr, all grades carbon	19
Low carbon 67 to 73 percent Cr, 0.025 percent carbon	24½
67 to 71 percent Cr. 0.05 percent carbon	23½
Charge chrome 61 to 66 percent Cr, 5.5 percent carbon	13½
Refined chrome 61 to 68 percent Cr, 4.25 percent carbon	22

TAXES

Producers of chromite ore and concentrate are granted a depletion allowance of 23 percent on income from domestic production and 15 percent on income from foreign production. In addition to the 15-percent depletion allowance, taxable income of operations outside the United States and within the Western Hemisphere is taxed at a lower rate, 14 points below the U.S. corporate income tax rate.

RESEARCH

Chromium resource investigations have included widespread search for ores, examination of deposits, and efforts to develop concentrating and utilization procedures for low-grade ores.

During World War II, Bureau of Mines and Geological Survey engineers and geologists investigated all known chromite sources in the United States to reduce the Nation's dependence on ocean transport. Under the Defense Production Act of 1950, financial assistance in exploration was offered through the Defense Minerals Exploration Administration (now the Office of Minerals Exploration); and a purchase program, through the Emergency Procurement Service of the General Services Administration, offered incentive prices to domestic chromite producers. Both of these programs stimulated widespread search and resulted in some production but brought little actual increase in total reserves.

Bureau of Mines scientists have conducted a number of studies on utilization of low-grade chromites. Mechanical and chemical methods of concentrating and smelting procedures for converting low-grade concentrate to usable ferrochromium have been investigated (*9–11*, *15*, *20*). A pilot plant, operated by American Chrome Co., Nye, Mont., produced as much as 13 to 14 tons per day of chromium ferroalloy from Montana chromite. Operations started in December 1958 and ended in 1961 (*8*).

Industry has made significant contributions to the more efficient use of chromium through the development of alloys, through improved smelting and fabricating techniques, and throughout the range of chromium or chromite applications. Improved electroplating techniques, development of catalysts, and adaptation of South African chromite for refractory use are noteworthy research accomplishments.

OUTLOOK

Major changes in the supply and use patterns over the next 10 to 20 years will involve increasing use of fines and concentrates, increasing interchangeability of use between the different chromite ore types, and increasing reliance on a relatively few large sources. Known world reserves of metallurgical- and chemical-grade chromite are more than adequate for many decades, but reserves of refractory-grade, high-alumina ores will be seriously depleted within 10 years.

Chromite resources in the Western Hemisphere will have little significance in the foreseeable future. In the next 10 to 20 years Rhodesia and the Republic of South Africa will gain in importance, while other traditional free world sources will supply a diminishing proportion of world requirements. The U.S.S.R. may continue as a major source of free world supply for decades, but subject to uncertainties regarding reserves and possible changes in governmental policy.

The major use of chromium by the domestic metallurgical industry is in stainless steel. The trend in stainless production relative to total steel (1950–63) suggests that by 1980, stainless may comprise 1.6 percent of total steel output, or about 2.3 million tons of the projected 147-million-ton total. This will require the equivalent of 1.0 million tons of chromite averaging about 48 percent Cr_2O_3. Other alloys will consume an additional 0.4 million tons, assuming continuation of the 1963 ratio. Thus the total consumption in 1980 by the domestic metallurgical industry will be about 1.4 million tons of chromite. Any shift to lower grade ores such as the 44 percent Transvaal ores will call for a corresponding increase in tonnage.

Consumption of chromite per ton of total steel, by the refractory industry, showed a slight downward trend in 1959–63, and the growing use of oxygen in steel production will accentuate this trend. However, assuming 3.5 tons of chromite per 1,000 tons of steel, consumption will increase from 368,000 tons of chromite in 1963 to more than 500,000 tons in 1980.

Based on anticipated growth rates for population (1.6 percent), labor force (1.6 percent),

and gross national product (3.8 percent), a growth rate of 2.0 percent for the chromium chemicals industry is assumed. This will increase consumption from 187,000 tons in 1963 to about 250,000 tons in 1980. Overall projected figures for 1980 are:

	Million tons
Metallurgical industry	1.4
Refractory industry	.5
Chemical industry	.25
Total	2.15

As a basis for comparison, about 26 pounds of chromite (all types) was consumed in 1963 per ton of steel produced by the domestic industry. Of this total, about 15.1 pounds was consumed by the metallurgical industry, about 3.4 pounds by the chemical industry, and about 7.5 pounds by the refractory industry. If applied to the projected 147-million-ton steel production of 1980, these factors would indicate a total U.S. chromite consumption of 1.91 million tons.

Imports of chromite (all types) to the United States in 1963 comprised 31 percent of world production. This was approximately the ratio of U.S. steel production to world steel production (25.7 percent) in the same year, and on this basis world demand in 1980 is estimated at three to four times the domestic requirement, or 6 to 8 million tons.

PROBLEMS

Almost complete dependence on foreign sources is the underlying cause for many of the supply problems faced by U.S. industry and defense planning agencies. These include price fluctuation, transportation problems, government instability in some areas, stockpile acquisition and storage problems.

Depletion of some traditional sources and the trend to interchangeable use of various chromite ore types present technical and economic problems to producers and consumers.

The brittle behavior of chromium metal and related problems in fabrication have restricted its use in some applications where its oxidation resistance might otherwise be used to advantage.

CLAYS

By James D. Cooper [1]

CLAY minerals are hydrous aluminum silicates, which are mixed in nature in varying proportions yielding a variety of clay types. The principal industrial clays are kaolin, ball clay, fire clay, bentonite, fuller's earth, and miscellaneous clay. About 57 percent of all industrial clay produced is used in manufacturing formed ceramic and refractory products and 34 percent in production of cement and lightweight aggregates; the remainder is used for fillers and numerous miscellaneous applications.

The total clay sold and used in the United States in 1963 was 50.2 million short tons valued at $181 million. Before World War I imported clays, particularly kaolins and ball clays, constituted an important part of the clay industry; now imports constitute only a small fraction of 1 percent of total U.S. consumption. The reverse trend has taken place with exports; formerly very little clay was exported, but since 1945 the exports have increased. The quantity exported is less than 2 percent of production but equivalent to nearly 12 percent of the value.

Georgia, Utah, and South Carolina are the main producing States for kaolin; Kentucky and Tennesse, for ball clays; and Georgia and Florida, for fuller's earth. Wyoming, South Dakota, Mississippi, Texas, and Arizona are the chief areas of bentonite production. The major part of production of fire clays is from Ohio, Pennsylvania, and Missouri, but there is substantial production from a number of other States. Miscellaneous clay is produced in all States except Alaska and Rhode Island.

Kaolin is used principally for paper and rubber fillers, refractories, and whitewares. Ball clay is used principally for whiteware, floor and wall tile, and refractories. Fire clay is used for refractories, heavy clay construction products and stoneware. Bentonite is used in foundry sands, drilling muds, absorbents, and iron ore pellets. Miscellaneous clay is used for heavy clay products, cement, lightweight aggregate, and in refractories and stoneware.

Specifications and tests vary with the type of clay and its properties and uses. Significant properties in ceramics are particle size, plasticity, fired color, strength, shrinkage, porosity, density, vitrification range, deformation temperature, bloating characteristics, and others. Properties important for nonceramic uses include: for the fillers—freedom from grit, particle size, color, and texture; for oil clarification—decolorizing ability and oil retention.

Until recent years methods of control and evaluation of clay properties were largely empirical, and simulated service tests often were cumbersome and time consuming. With increasing production and demand for better products the need for more precise controls and manufacturing procedures has brought about intensive research in governmental, educational, and private institutions. Study of the fundamental crystalline structures, effects of impurities, and other factors has revolutionized concepts and resulted in better scientific controls and tests.

The outlook is for increasing demand for better refractory and ceramic materials. Total clay production and consumption will continue to increase at a somewhat lower rate than gross national product (GNP), but individual classes of clay will not necessarily follow the same growth pattern because of changing technology, new uses, and changes in architectural styles.

[1] Commodity specialist.

BACKGROUND

SIZE, ORGANIZATION, AND GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

Because of the widespread occurrence of brick and pottery clay there are few areas of the world that do not have some sort of clay industry. In the United States 50.2 million tons of clay, valued at $181 million, was produced in 1963 from 1,300 mines by about 1,000 firms. Almost 900 of these firms produce miscellaneous clay used principally for heavy clay products (building brick and tile, sewer pipe, and terra cotta) lightweight aggregates, and portland cement, or fire clay, for use in refractories and heavy clay products. The U.S. clay industry employs about 4,500 in mine production and approximately 150,000 in processing and manufacturing clays and clay products. In 1963, about 97 percent of all miscellaneous clay and 70 percent of fire clay mined in the United States was from mines owned or controlled by consumers. Essentially all of the bentonite, fuller's earth, kaolin, and ball clay produced in 1963 was mined by about 90 firms in 24 States, primarily engaged in mining and preparing the materials for the market.

Georgia and South Carolina, for many years the major producers of kaolin, supplied about 94 percent of the total annual output during 1959–63. Production was reported from eight other States. Most of the domestic ball clay production in this same period, came from western Tennessee and Kentucky, with smaller quantities reported from California, Maryland, and Mississippi.

During 1959–63 fire clay output was reported from 29 States. Ohio, Pennsylvania, Missouri, and Texas, in that order, were the major producers, supplying about 65 percent of the total.

Bentonite production in 1959–63 was principally from Wyoming, Mississippi, and Texas; fuller's earth was produced mainly in Florida, Georgia, Mississippi, and Tennessee.

Miscellaneous clay and shale were produced in nearly all States and in 1959–63 furnished about 71 percent by quantity and 25 percent by value of the total domestic clay production.

DEFINITION OF TERMS, GRADES, AND SPECIFICATIONS

Clays are earthy mineral aggregates consisting essentially of hydrous aluminum silicates which are plastic when sufficiently pulverized and wetted, rigid when dry, and vitreous when fired at a sufficiently high temperature. The term clay is sometimes loosely used for all fine grained material—about 2 microns or less—regardless of plasticity.

Shales used in the ceramic industry are products of consolidation of clays under pressure. When pulverized and wetted, these shales become plastic or otherwise regain the characteristics of clays.

Types of Clays

Clays are classified in six groups in Bureau publications. These are kaolin, ball clay, fire clay, bentonite, fuller's earth, and miscellaneous clay.

Kaolin is a mineralogical term referring to a clay in which the predominant clay mineral is kaolinite. China clay is used synonymously with kaolin. Halloysite, although differing somewhat in chemical composition and lattice structure, is included under kaolin in Bureau statistical reports. Commercial kaolins have a nearly white dry and fired color. Grades of kaolin are determined by intended uses in whitewares, rubber, paper, refractories, and other products. Specifications are based on the method of preparation (crude, air separated, water washed, air dried, spray dried, slip, pulp, slurry, or water suspension) and on specific physical and chemical properties.

The term ball clay originated from the unusually high plasticity of clays so named, which enabled them to be rolled readily into balls. In early mining practice, mostly by hand labor, the material was rolled into balls, then thrown into wagons. Ball clays consist principally of kaolinite, but have a higher silica-to-alumina ratio than is found in most kaolins as well as larger quantities of mineral impurities and much organic material. They are usually much finer grained than kaolins and, in general, set the standards for plasticity. The fired products are generally not as white as those made of kaolins.

Specifications for ball clays are based on methods of preparation (crude, shredded, air floated) and pertinent physical and chemical tests, which are much the same as those for kaolin (*6*, *24*).[2]

The terms "fire clay" and "stonewear clay" are based on usage—fire clay indicating use for refractories, and stoneware clay indicating use for such items as crocks, jugs, and jars. Fire clays are basically kaolinitic but usually include other clay minerals such as halloysite and illite, and both organic and inorganic impurities. In-

[2] Italicized numbers in parentheses refer to items in the list of references at the end of this chapter.

cluded under the general term fire clay, are the diaspore, burley, and burley-flint clays. Diaspores are largely aluminum hydrates ($Al_2O_3 \cdot H_2O$). The burley clays contain burls (oölites or nodules) and are varieties of diaspores with some halloysite and kaolinite. The burley flint clays contain small oölites predominantly of halloysite, with some kaolinite and diaspore. The fired colors of fire clays range from reds to buffs and greys.

Based on relative plasticity and hardness, the following types of fire clay are recognized by the trade: Plastic, semiplastic, semiflint, flint, and nodular flint. Several recognized types also are defined according to use: Among these are stoneware, tile, refractory, and heavy-clay-product clays. Specifications are based on pertinent physical and chemical tests of the clays, and of products made from them (*24*).

Bentonite was named from a deposit in the Fort Benton shale in Wyoming, where the material was first recognized as a separate type of clay. Bentonites are composed essentially of minerals of the montmorillonite group. Two types are recognized—the swelling and nonswelling (meta- or sub-bentonites). The swelling type is the only clay that will increase materially in volume when wetted with water. It is high in sodium, whereas the nonswelling types are high in calcium. Standard grades of swelling bentonite increase from 15 to 20 times their dry volume. Foundry sands and drilling muds compose the two main grades of the swelling types. In recent years iron ore pelletizing has grown rapidly, requiring large quantities of the swelling bentonite as a binder. Nonswelling bentonites are used for bleaching, filtering and catalysis by the petroleum industry, and in foundry sands. The specifications are based on pertinent physical and chemical tests, particularly those relating to particle size and swelling index (*1, 4, 40, 44*).

The term "fuller's earth" is derived from the first major use of the material, which was for cleaning textiles by fullers. Fuller's earths are essentially montmorillonite or attapulgite. The montmorillonite fuller's earths closely resemble sub-bentonites and tend to be high in magnesium (*33*). Fuller's earths have almost the same grades as those of nonswelling bentonites, except that they are not used in foundry sands. An additional important grade is that of absorbent (floor sweep). Specifications are based on the physical and chemical tests of the products (*3, 24*).

The term "miscellaneous clay" is a statistical designation used by the Bureau to refer to clays and shales not included under the other five clay types. Miscellaneous clay may contain some kaolinite and montmorillonite but illite usually predominates, particularly in the shales. There are no specific recognized grades based on preparation, and very little based on usage, although such a clay may sometimes be referred to as common, brick, sewer pipe, or tile clay. Specifications are based on the physical and chemical tests of the products (*7, 24*).

Specifications

Specifications of clays are based on end uses. Although many specifications have been established by the American Society for Testing and Materials (*5, 6, 7*), American Foundrymen's Association (*1*), American Oil Chemists Society (*3*), American Petroleum Institute, Technical Association of the Pulp and Paper Industry (*46*), and other national organizations, many producers and consumers rely on their own tests and specifications applicable to their specific needs (*24*). The tolerance limits of mineralogical composition, particle size, and other physical and chemical properties also are determined largely by individual requirements.

For use in ceramic wares, the important properties are plasticity, fired color, dry and fired strength, drying and firing shrinkage, and the vitrification range (the range of temperature at which, for a given method of forming and schedule of firing, minimum volume and porosity are maintained without appreciable change).

For refractory uses, the most significant single property is the pyrometric cone equivalent (PCE), which is determined by comparing the softening behaviour of a clay sample subjected to a standard time-temperature schedule with that of standard cones. Clays having a PCE of 33 (3,169° F at 270° F heating rate per hour), or higher are used for manufacturing superduty refractories; those with a PCE of 31 (3,061° F) up to 33, for high-duty refractories; and those with a PCE of 30 (3,029° F) up to 31, for low-duty refractories. Serviceable refractories for some purposes can be made from clays having a PCE as low as 15 (2,606° F).

Clays for refractories not only must have an acceptable PCE but also when made into standard refractory brick by commercial forming processes, must meet high-temperature load and spall tests (ASTM Designations C–16 and C–122, respectively) (*7*). These tests, as well as many other ceramic end-product tests that reflect the properties of the raw materials used, are time consuming, cumbersome, and expensive.

Clays or shales (and slates) for producing thermally expanded lightweight aggregate must become pyroplastic and full of fine gas bubbles when heated to the appropriate temperature

range, preferably 1,800° to 2,200° F. Nonexpandable clays and shales are used in production of lightweight aggregates by sintering clay mixed with coal or other combustible materials that will burn out, leaving voids.

Clays used in manufacturing cement are selected to supply deficiencies in chemical composition, such as silica, iron oxide, and alumina not present in the available limestone or cement rock.

The most desirable clays for rotary-drilling muds are those which swell when wetted with water.

Filtering and decolorizing clays have high sorption such as characterize the montmorillonite and attapulgite groups of minerals.

For filler clays and paper coating clays, emphasis is on fineness of grain and whiteness of dry, unfired clay; for insecticide carriers high adsorption is important.

TECHNOLOGY

Mineralogy and Geology

Natural clays consist of many different minerals, but certain minerals or classes of minerals occur in all clays and are called clay minerals. Mineralogically the clay minerals have been classified as hydrous aluminum and magnesium silicates. The names, chemical composition, and optical properties of these silicates are given in table 1.

Of the clays used by the ceramic industry the kaolin group is the most prevalent. Kaolinite, halloysite, dickite, and nacrite are the principal minerals in this group.

The montmorillonite minerals are less common than kaolins but comprise an important group of clay minerals. With the addition of water, some minerals of this group swell, resulting in increased volume. The best known example of this phenomenon is the swelling bentonites. Montmorillonite, nontronite, and volchonskoite form one series where silica, alumina, magnesia, iron oxide, and water are the principal components. Volchonskoite contains about 15 percent chromium oxide, Cr_2O_3. Saponite and hectorite make up another series containing chiefly magnesia, lithia, silica, and water. Illite represents an important but not too well understood mineral group.

The magnesium silicate group of palygorskite (attapulgite) and sepiolite is much less common than the other groups. The minerals are essentially hydrated magnesium silicates.

Geologically, clays are of two general types—residual and transported; but in all instances clay is of secondary origin, having been formed by the alteration of other rocks. Clays may be found in a variety of forms—as a soft paste, soft solid (mudstone), or as laminated rock (shale). They may occur at or near the surface or at relatively great depths. The kaolinitic clays of commerce are derived largely from feldspathic rocks and the bentonites and fuller's earths from volcanic ashes. The decomposition is usually a result of weathering, although hydrothermal reactions are responsible in many instances. Shales and flint fire clay are clays that have been compacted and hardened by metamorphic processes.

Some china clay and bentonite deposits are formed by weathering of rocks in place, but most commercial deposits have been transported.

TABLE 1.—*Physical properties of the clay minerals* (*33*, *42*)

Name	Composition	Optical properties							
		Crystal system	Specific gravity	Hardness	Refractive index	Birefringence	Interference figure	Crystal habit	Color
Kaolin group:									
Kaolinite	$Al_2(Si_2O_5)(OH)_2$	Triclinic	2.61	2.0	1.56	0.006	B-neg	Plates	None.
Halloysite	$Al_2(Si_2O_5)(OH)_2$	Hexagonal(?)	2.62		1.52	.030	do	Small needles.	Do.
Livesite	$Al_2(Si_2O_5)(OH)_2$	Monoclinic	2.63		1.54	.020	do	Small plates.	Yellow(?).
Dickite	$Al_2(Si_2O_5)(OH)_2$	do	2.62	2.5	1.56	.006	do	Plates	None.
Nacrite	$Al_2(Si_2O_5)(OH)_2$	Orthorhombic	2.54	2.5	1.56	.006	B-neg(?)	do	Do.
Anauxite	$Al_2O_3 3SiO_2 2H_2O$		2.60						
Allophane	$Al_2O_3 \cdot nSiO_2 nH_2O$				1.49		Isotropic		
Montmorillonite group:									
Montmorillonite	$(Al,Mg)_2Si_4O_{10}(OH)_2$	Monoclinic	2.50	2.0	1.51	.021	B-neg	Small flakes.	None.
Nontronite	$(Al,Fe,Mg)_2(Al,Si)_4O_{10}(OH)_2$	do	2.60	2.0	1.56	.023	do	Small laths.	Brown.
Hectorite	$(Mg,Li,Al)_3Si_4O_{10}(OH)_2$	do	2.4	2.0	1.49	.022	do	Small flakes.	None.
Saponite	$Mg_3(Al,Si)_4O_{10}(OH)_2$	do	2.5	2.0	1.50	.015	do	do	Do.
Hydromica (illite)	Variable	do	2.75		1.57	.021	do	Plates	Do.
Magnesium silicate group:									
Sepiolite	$H_4Mg_2Si_3O_{10} \cdot nH_2O$	Orthorhombic	2.0	2.0	1.53	.010	U-neg	Small fibrous.	Do.
Palygorskite(attapulgite)	$Mg_5Si_8O_{20}(OH)_2 \cdot 8H_2O$	do			1.51	.020		do	

Mining

Most clays and shales are mined by open-pit methods. Some deposits are mined by underground methods, usually room-and-pillar, through adits or inclined shafts. Steeply dipping refractory clay beds east of the Front Range in Colorado are mined by shrinkage stoping. Hand methods are still used at many small mines. In recent years improvements in earth-moving equipment have greatly extended the economic depth of surface mining. For example, many of the northern Missouri fireclay deposits that up to a few years ago were mined by underground methods are now being operated as open pits, with overburden-to-clay ratios as high as 10:1.

Some kaolin deposits are mined by hydraulicking. The clay is washed down by jets of water and the clay-water suspension is raised to the surface by pumping or in bucket elevators. It may move from the surface to the refining plants by gravity flow or by pumping. Kaolin slurries are sometimes pumped substantial distances (10 to 12 miles). The usual procedure in Georgia is to collect the material at a blunger (mixer) near the mine, add a deflocculant, and then pump the slurry to the refining plant. In one plant a primary portable blunger is used at the pit before the main blunger. Rubber-lined conduit is used.

Little blasting is required in clay or shale mining, except in some fire clay mines. Shale planers are used at some open-pit mines. Transportation of mined clay to plant bins or stockpiles is usually by truck, but conveyor belt or railroad transportation is used where applicable.

Processing

Kaolin

Kaolin may be marketed after crushing and screening or air separation. More often, after preliminary crushing and screening, sand, mica, and other impurities are separated by sedimentation in water and the clay is then recovered by thickening, followed by filter-pressing and heated air drying. Within the last decade, however, spray drying has largely superseded the filter press, particularly for paper fillers and coaters. After bleaching with sulfurous acid the material is spray dried. Some kaolin for enamel, paper coating, and other usage is reduced to such fine particles that only a small percentage of the total production exceeds 1 or 2 microns in maximum dimension.

The coating clays differ essentially from most filler clays in grain size, and additional bleaching is usually required. The filler and coater portions of a clay are separated by classification sizing, the very fine being coater, the coarser being filler. In some clays the proportion of grain fine enough for coater is comparatively small. Conventional fine grinding and micronizing are relatively costly. An experimental grinder and process developed by the Bureau has shown considerable promise for production of coating clay from low-grade material, and a number of the kaolin producers have built similar grinders and are continuing to refine the process.

Paper clays after spray drying are loaded directly into covered gondola cars for shipment. Formerly, these clays were shipped mostly in tank cars as slurry containing about 70 percent solids, or as dry clay, in bulk, in lined boxcars. For ceramic purposes, dry clay is usually ground and bagged for shipment but is sometimes transported in lump bulk form.

Ball Clay

Ball clay from the pit usually is dumped into a shredder, consisting of a bowl suspended over a revolving slotted plate to which knives are attached. The weight of the clay forces it against the knife, and as each piece is cut off it drops through the slot to a belt and is delivered to storage.

Ball clays are shipped as air-dried lump clay, air-dried shredded clay, semidried shredded clay, or dried pulverized and air-floated clay. Semidried ball clay is obtained by processing in rotary driers. Coarse sand and lignite are removed by air separation. Lump and shredded ball clay usually is shipped in bulk, and pulverized and air-floated ball clay is shipped in bags.

Fire Clay and Miscellaneous Clay

Primary crushing of fire clay, miscellaneous clay, and shale usually is done with jaw or gyratory crushers, rolls, or hammer mills. For ceramic products, secondary crushing and grinding are quite generally by dry pan, occasionally by wet pan. Dry and wet pans are similar to chaser mills. Dry pans operate continuously and discharge the crushed clay through a screen bottom. In wet pans batches of clay or shale are ground with water to the desired consistency. Secondary crushing is usually followed by screening. A rotary drier sometimes is used ahead of the screens. After crushing and screening the material may be fed into a pugmill and an extrusion machine. Where dry presses are used in making the final product, the crushed and screened material is fed into mixers and then directly to the press.

Clays and shales used for production of lightweight aggregate by the rotary kiln method are usually crushed to the proper size, screened, and fed to storage hoppers or directly to the kilns. Fines from the crushing operation may be utilized by pelletizing, or in some cases by allowing clay fines to recompact by natural weathering. At some plants the fines are wasted.

In the sintering furnace method the clay or shale is pelletized, usually with the addition of coal dust or other combustible material, and the pellets passed through an ignition zone where the combustibles are burned out, causing partial fusion of the clay, and leaving voids which account for the low weight.

The sintered material and much of the rotary kiln aggregate, is crushed to the required sizes for use in concrete.

In the cement industry primary crushing is the same as for structural clay products. Secondary crushing and grinding is done in ball or rod mills to insure the necessary fine grain (minus 200-mesh), after which the material is screened and ready for the rotary kiln. Both wet and dry processing are used.

Bentonite

Preparation of bentonite consists of drying, with care to avoid overheating, and grinding by ball, rod, or roller mills to specific sizes, including air-floated material. About 10 sizes are marketed, ranging from 20-mesh to minus 1,500-mesh. Most bentonite is shipped in bags.

Fuller's Earth

Fuller's earth is processed by feeding directly to a single-roll crusher as it comes from the mine. The screened material is conveyed to storage bins, then fed by mechanical feeders into pugmills. The clay is extruded from the pugmills through perforated steel plates into rod or spaghetti-like forms from ½- to ¾-inch diameter. The extrusions are conveyed to a rotary dryer. From the dryer the clay is screened to pass 8-mesh, the undersize going to a series of three bolting machines (steel-roll and sifter combinations) with provision for recirculating the oversizes. These bolting machines are the same as those used in flour mills. Each roll mill grinds a little more of the clay to the desired sizes, and each sifter separates the oversize from the market products which are minus 15-, plus 30-mesh; minus 30-, plus 60-mesh; minus 60-, plus 90-mesh; and minus 90-mesh. Fuller's earth for insecticide use is ground in roller mills. Fuller's earth used for floor sweep is calcined in rotary kilns and screened to eliminate particles finer than 16-mesh. Fuller's earth is shipped in bags.

USES

Clays may be used in the raw or unfired condition or as a fired product. Color, texture, bonding strength, and absorptive qualities of the clay govern its use as an unfired material. Some of the major uses of fired clays are as refractory, structural, and decorative materials. The names given to certain types of clay such as china, brick, stoneware, or terra cotta refer only in a general way to their properties. A clay suitable for brick can be used to make drain tile. Clay products such as architectural terra cotta and chemical stoneware are usually made from mixtures of clays. Whiteware bodies contain kaolin, ball clay, talc, quartz, and feldspar.

The paper, rubber, refractories, and pottery industries are the principal kaolin consumers. The paper industry, which utilizes kaolin both as a filler and coater, is the largest single consumer, using half of the total output. Chemicals, cosmetics, insecticides, petroleum catalysts and miscellaneous uses account for about 8 percent of the total.

Pottery, stoneware, and floor and wall tile are the major uses of ball clay. Refractories, art pottery, saggers, and kiln furniture require smaller quantities.

Fire clay is used primarily in heavy clay products and refractories, which take approximately 95 percent of the total output. Fillers, drilling muds, and chemicals account for most of the remainder.

More than 55 percent of the bentonite production goes into rotary drilling muds and foundry sands and facings. The most important new use is as a bond in pelletizing iron ore concentrate.

Absorbents, insecticides and fungicides, and drilling muds, in that order are the major products requiring fuller's earth. These uses take about 85 percent of the annual output.

Heavy clay products such as building brick, sewer pipe, drain tile, and similar products take more than 50 percent of the output of miscellaneous clay. Portland cement and lightweight aggregate are the other major products requiring this type of clay, with less than 2 percent going to other uses.

BYPRODUCTS AND COPRODUCT RELATIONSHIPS

Mica, silica sand, and bauxite are obtained as byproducts or coproducts in processing kaolins. Some of the sand produced is suitable for building materials. The mica is of the type used in producing ground mica. No byproducts or coproducts are obtained from other types of clays.

Coal-measure clays or shales, however, are sometimes mined in conjunction with coal.

Clays have many commercial and technological relationships to other mineral commodities. In some of these interrelated industries, clays occupy a primary function in manufacturing finished products, for example, cement, lightweight concrete, and drilling muds. In others clay may be only one of several satisfactory raw materials available. The quantities of kaolin and ball clay used in the production of whiteware affect the demand for feldspar, ground silica (potter's flint) and various other mineral components. There is also an interdependence of the fire-clay refractories industry and the metallurgical industries.

High-alumina clays (fire clay and kaolin) are a potential source of alumina for aluminum production, but costs are too high for clay to compete with bauxite for this purpose in the United States. In 1958, however, The Anaconda Company began operating a 50-ton-per-day pilot plant in Anaconda, Mont., to produce aluminum-grade alumina from the clay of Latah County, Idaho, and in 1963 aluminum was produced on an experimental basis in two pots using alumina produced from Latah County clay. Also in 1963 several thousand tons of Georgia kaolin was shipped to Anaconda for experimental alumina production.

Clay or shale is utilized to balance the alumina and silica content of the raw-material mix at many cement plants.

Fire clay and kaolin have a complex relationship with a wide variety of other refractory materials, including silica, dolomite, mullite, magnesite, chromite, graphite, pyrophyllite, bauxite, olivine, silicides, carbides, nitrides, borides, and rare-earth oxides. Considerations governing the selection of a specific refractory, in addition to PCE, are bonding qualities, load-bearing strength under operating temperatures, and resistance to spalling and slagging. The relationship of refractory clays to bauxite is close, as many refractory products are made from mixtures of clay and bauxite.

ALTERNATE MATERIALS

For ceramic purposes there are no direct substitutes for clays, although there are alternate materials for almost all clay products. Wood, glass, concrete, plastics, various metals, and other materials may be used in place of ceramic clay products.

For most nonceramic uses there are alternate materials. For example, carbon black has replaced clay to some degree as a filler in rubber for tires and certain other rubber products. Several materials, such as talc, gypsum, and chalk, may be used partially to replace clay as paper fillers. Several substitutes have been found to replace fuller's earth and bentonite as oil clarifiers. In many nonceramic uses, clays are used because they are less expensive than other materials having equal or better qualifications.

Bauxite replaces fire clay in refractory uses and activated bauxite competes with activated bentonite and fuller's earth in mineral oil bleaching and filtration. Cinders, blast-furnace slag, pumice, and perlite are substitutes for expanded clay and shale lightweight aggregate in some uses. Argillaceous limestone (cement rock), where available, reduces or eliminates the need for clay in manufacturing cement.

RESERVES

Clay resources in the United States are sufficient to supply essentially all requirements for the next century with exception of fire clay.

Miscellaneous clays and shales suitable for production of clay construction products and cement occur in all States. Many of the deposits contain material suitable for production of lightweight aggregates, and a systematic study is under way to locate suitable clays and shales for this purpose (*11*, *14*, *17*, *19*, *29*, *31*, *45*).

Bentonite deposits in Wyoming, Montana, and South Dakota contain several hundred million tons of minable reserves (*25*, *26*). Deposits also occur in Mississippi, Texas, and other States.

There are large deposits of attapulgite fuller's earth in Florida and Georgia. Montmorillonite fuller's earth occurs in large quantities in Mississippi and western Tennessee and Kentucky. Other deposits of fuller's earth are in Utah, Texas, California, and Nevada. Quantitative ore reserve data are not available.

The largest domestic ball clay deposits are in Tennessee, Kentucky, and Mississippi. Other deposits are in California and Maryland.

Kaolinitic clays are widespread in the central and eastern States, and most deposits are of ceramic-grade material. High-grade kaolin deposits containing paper coating and filler quality materials are mostly in Georgia and South Carolina with smaller deposits in Alabama, California, Connecticut, Florida, and other States.

Fire clay resources are found in most areas of the United States, and deposits in about 30 States have been exploited in recent years. Although the overall reserves are large, the super duty and high-heat duty clays in some areas are becoming exhausted. The Missouri fire clay districts are a notable example, and re-

search is being conducted toward removal of detrimental impurities from material representing large deposits of presently submarginal but potentially high-grade fire clays (*8*, *38*, *39*).

CONSERVATION

Because of the relatively large supply of clays, little effort has been directed toward conservation. However, there is substantial interest in the possibility of expanding the supply of high-grade refractory and paper clays by beneficiating inferior clays, which would extend the productive life of the existing high-grade kaolin and refractory-grade clay deposits. The Bureau has recently conducted research to this end with encouraging results.

SOURCES OF STATISTICAL INFORMATION

Clays-production statistics are obtained and tabulated by the Bureau of Mines from all known producers. The Bureau of the Census compiles and publishes monthly statistics of the quantity and value of shipments of the principal structural clay products in the United States and quarterly reports on the production and shipments of clay and nonclay refractories, by type (*47*, *48*). The Department of Commerce also compiles data on imports of various types of clay. Data on exports from the United States are obtained by the Bureau of the Census and from producers canvassed by the Bureau of Mines. Data on production and import-export trade in foreign countries are obtained from various sources, including mineral industry reports gathered by the Department of State. These data are adequate for most U.S. Government and industry purposes. Canadian Government statistics are exceptionally complete and reliable and provide a sound basis for evaluating the interrelationships between the United States and Canadian clay industries.

PRODUCTION, CONSUMPTION, AND TRADE

Detailed data on kinds of clay sold and used, and the quantities going for major uses are shown in table 2. The production of clays of various kinds was reported from 48 States, and the District of Columbia in 1963 (see table 3). Alaska and Rhode Island were the only States not reporting. Miscellaneous clay was recovered in all reporting States, and fire clay in 29 States. About 60 percent of the total clays sold or used was reported from 10 States—Ohio, Georgia, Texas, California, Pennsylvania, North Carolina, Michigan, Illinois, Missouri, and Alabama. The same 10 States accounted for 63 percent of the clay value. Consumption of clays for 1949–63 is given in table 4.

Nonceramic uses accounted for 43 percent of all clays consumed in 1963, compared with 38 percent in 1959 and 32 percent in 1954. The major factor causing the increase in nonceramic use was the production of expanded clay and shale aggregates which required 13.5 percent of total clays consumed in 1963 compared with 3.6 percent in 1954. With minor exceptions the percentages required for other nonceramic uses have remained constant during the past decade.

U.S. imports of clays have not been a significant factor in the industry in recent years. Before World War I, most of the kaolin and ball clays used in the United States were imported, principally from England, but domestic material now dominates the market for all types of clay, except in areas where the freight differentials favor imports and where consumers prefer the imported clays. Small quantities of all types of clays, except miscellaneous clay, are imported from the United Kingdom, West Germany, Canada, and other countries. Total imports of clays into the United States in 1963 were 126,000 tons, valued at $2.4 million. Beginning in 1954 separate data have been available only for kaolin and common blue and ball clays.

Exports from the United States include kaolin and fire clay for which separate data are available. Bentonite and fuller's earth probably comprise the greater part of the balance of clay exports but they are not reported separately. In 1963, total clay exports were 739,000 tons valued at $21 million, representing less than 2 percent of the total U.S. production, but nearly 12 percent of the value.

Under paragraph 207, schedule 2, of the Tariff Act of 1930, clay or kaolin, bentonite, fuller's earth, and clays or earths artificially activated are dutiable. In addition, some other kinds of clays are dutiable under the category of "clays or earths, including common blue clay and Gross Almerode glass-pot clay, n.s.p.f. (not specifically provided for)." The clays in the latter category include low-grade building-brick clays, high-grade ball clays, stoneware clays, and fire clays. In the latest tariff schedules ball clays have been separated from this blanket category. The history of tariffs on the dutiable classes of clays is given in table 5.

TABLE 2.—*Clays sold or used by producers in the United States in 1963 by kinds and uses*

[Short tons]

Use	Kaolin	Ball clay	Fire clay and stoneware clay	Bentonite	Fuller's earth	Miscellaneous clay including slip clay	Total
Pottery and stoneware:

STRATEGIC CONSIDERATIONS

The United States is self-sufficient in clays, although cost and consumer preferences provide a relatively small market for a few types of imported clays. As the Missouri diaspore and burley clays are exhausted some consumers are placing increasing reliance on bauxite from Caribbean sources for use in manufacturing high-alumina refractories. Bauxite clays from the Caribbean area also could be utilized extensively in future production of lower duty refractories.

No defense programs have been required for clays, although a strategic stockpile of refractory-grade bauxite has been established to provide material for high-alumina refractories if shipments from British Guiana and Surinam should be interrupted in wartime.

TABLE 3.—*Clays sold or used in the United States in 1963, by States, and by kinds*

[1] Included with undistributed to avoid disclosing individual company confidential data.
[2] Less than 500 tons.
[3] Incomplete total because of concealed data for some types of clay.

PRICES AND COSTS

Prices quoted in Oil, Paint and Drug Reporter for December 1963 for various clays were as follows:

Bentonite:
200-mesh, bags, carlots, f.o.b. mines, per short ton, $14.

Fuller's earth (February 1960):
Insecticide grade, dried, powdered, bags, carlots, Georgia or Florida mines, per short ton, $17.50.
Oil-bleaching grade, 100-mesh, bags, carlots, per short ton, $16.30–$17; 200-mesh, bags, carlots, per short ton, $17.50–$18.

Ball clay:
Domestic, air-floated, bags, carlots, Tennessee, per short ton, $18–22; crushed, shed moisture, bulk, carlots, Tennessee, per short ton, $8–$11.25.
Imported, air-floated, bags, carlots, Atlantic ports, per ton, $43–$47; lump, bulk, carlots, Atlantic ports, per ton, $31.50–$37.50.

China clay:
Domestic, dry-ground, calcined, air-floated, bags, carlots, f.o.b. plant, Georgia, per short ton, $43–$68; dry ground, air-floated, 99 percent 325-mesh, bags, carlots, f.o.b. plant, Georgia, per short ton, $11–$17; water-ground, washed, bags, carlots, f.o.b. plant, per short ton, $21.50–$50.
Imported, white, lump, bulk, carlots, ex dock, Philadelphia, Pa., and Portland, Maine, per long ton, $23–$35; powdered, bags, carlots, ex dock, per short ton, $50.

The quoted prices indicate only the range of prices. Actual prices are subject to individual negotiation between buyers and sellers, and depend on the degree of processing, type of packaging, and many other factors. Prices for fire clay and miscellaneous clay, a large proportion of which is produced in captive operations, are not quoted in trade journals.

Changing practices in past reporting of unit values make it almost impossible to arrive at reliable long-term comparisons. However, prices have remained fairly constant for relatively long periods.

TABLE 4.—*Clays sold or used by producers in the United States for ceramic and nonceramic uses*

[Thousand short tons]

Uses	1954	1955	1956	1957	1958	1959	1960	1961	1962	1963

[1] Effective Jan. 1, 1964.

TAXES

No special taxes are imposed on the clay industry. Producers of kaolin, ball clay, bentonite, fuller's earth, and fire clay are granted a depletion allowance of 15 percent on both domestic and foreign production. Producers of brick and tile clay are granted an allowance of 5 percent for foreign and domestic production.

TRANSPORTATION

Transportation is a relatively small factor in the clay-processing industries. Most of the miscellaneous-clay and fire-clay processing plants, which use about 90 percent of the clay consumed annually, obtain their supply of raw material from deposits adjacent to the plant. Only the relatively high-grade ball clays, kaolin, bentonite, and fuller's earth are transported long distances to consuming centers.

Transportation is a major factor in marketing of brick, tile, lightweight aggregates and other clay construction products. Only in special cases can the marketing radius exceed a few hundred miles.

RESEARCH

Research on clays is presently being conducted by a large number of public and private organizations and for a diversity of purposes. Geologic correlations are frequently made on the basis of the types and quantities of clay minerals present, and much work on this subject is conducted by Federal and State geological surveys, and by universities. Much work is done by the Federal Bureau of Mines, National Bureau of Standards, and by private industry on improvement of clays for ceramic and other purposes by beneficiation for removal of impurities, and on modification or improvement of clay minerals by heat treatment and by reaction with organic and inorganic chemicals. New methods for identification and study of clay minerals are being developed, and the structure of clay minerals is receiving a large share of attention by researchers.

During World War II the Bureau of Mines did exploratory work to find high-alumina clays and conducted extensive pilot-plant research and investigation to produce alumina suitable for manufacturing aluminum from clays. Several different processes were tried. The Bureau of Mines is presently evaluating a number of alumina-from-clay processes developed by Government and industry to determine which has the most merit.

During the past decade the Bureau has conducted research on beneficiation of refractory and paper clays and the evaluation of clays and shales for thermally expanded lightweight aggregate and other uses. Surveys were completed by the Bureau on refractory clay deposits in a number of western States and on expandable clays and shales in many of the North Central States. Similar studies were under way in other areas. Technologic and economic studies are coordinated to assist industry in assuring adequate supplies of clays at minimum cost to meet national, regional, and local requirements.

OUTLOOK

Production of clays in general should continue to climb approximately in proportion to the GNP but at a slightly slower rate. Many of the individual types of clays are subject to fluctuations from factors which bear no direct relationship to the GNP.

Bentonite production in Wyoming is in a period of rapid expansion due to conversion of iron ore processing facilities in the United States and Canada for production of high-grade iron ore pellets using bentonite as a binder. Legislation providing for an equitable taxation arrangement between the State government and the iron ore producers in the Minnesota taconite areas was passed in 1964, and this should further accelerate bentonite production for pelletizing.

Production of clay and shale for lightweight aggregates will probably continue to increase at a rate somewhat above that of the GNP but not as rapidly as it has during the past 10 years. As indicated by recent practice, new plants will be larger and more efficient.

Use of fire-clay refractories should continue to decrease for several years due to many factors. Increased labor costs have made it necessary for many refractories users to switch to more expensive refractories with long service life to minimize maintenance and replacement costs. The rapid conversion of steel plants to the basic-oxygen processes has reduced the requirements for fire-clay refractories. Furthermore, the operating temperatures now prevalent in many nonferrous metallurgical plants are higher than the rated limits of fire clays. Exhaustion of fire-clay reserves in some areas of the United States has accelerated the use of other refractories.

The consumption pattern for fuller's earth is changeable and will probably continue to be so. However, due to its versatility the demand for fuller's earth is expected to continue to increase at a rate somewhat higher than that of clays in general. Absorbent uses which are growing rapidly, should account for over half of the production during the next 5 years. Use of fuller's earth as a soil conditioner on golf courses and sports arenas is also expected to increase rapidly.

Paper coating and filler will continue to account for the greater part of kaolin produced in the United States, with other fillers, refractories, high-quality ceramics, and chemicals taking the balance. An annual growth rate of 5 to 6 percent is indicated.

Ball-clay production should increase 3 to 4 percent per year for the next 5 years.

Output of clays and shales for brick, tile, and other clay construction products should remain fairly constant, with possible slight increases over the next 10 years due to the improving competitive position of the structural clay-products industry.

PROBLEMS

Perhaps the most important problem confronting the clay industry is in structural clay products, where the intense competition from other construction materials is threatening, and in some cases replacing, clay brick and tile. The principal competing products are glass, metals, and conventional and special concretes.

Fire clay and fire-clay refractories industries are threatened from several directions. In some local areas the high-grade fire-clay deposits are becoming exhausted. Competition from other refractories is increasing because of technologic changes and because of the higher maintenance and replacement costs involved with the fire-clay products. In local areas where common clays are not readily available or where there is no current demand for fire clay for refractories production, fire-clay deposits are being depleted by use of this material in clay construction products.

Bentonite is being used in increasing quantities for pelletizing iron ore concentrates, and new mining and processing facilities are being built in Wyoming to provide the material. However, the transportation cost to some pelletizing plants exceeds the basic cost of the bentonite, and new, lower cost binders are being sought, which could adversely affect the growth of the bentonite producing industry.

Much low-grade kaolin is produced along with material of paper coating quality in the South Central States. Improvement of the low-grade material by fine grinding is technically feasible, but economic large-scale processing facilities have not yet been developed. Until this problem is solved much potentially valuable material will be wasted or sold for low quality filler and ceramic uses.

Data are lacking in many States on the quantities and qualities of clay and shale suitable for production of expanded lightweight aggregates. Lack of adequate data on potential markets for lightweight clay and shale aggregate in some areas also prevents the optimum growth of the lightweight aggregate industry.

COBALT

By Glen C. Ware [1]

THE history of cobalt dates to ancient times. Its earliest use was solely as a coloring agent which imparted the brilliant blue hue to early ceramics and glass. The Chinese developed the art of cobalt coloring to a high degree during the Ming Dynasty. In Europe the Venetian artisans of the 15th century were using various cobalt compounds to color their renowned glassware.

Chief minerals of cobalt are in four major categories—arsenides, sulfides, sulfarsenides, and oxidized minerals. Large deposits occur in Canada, Cuba, Morocco, Northern Rhodesia, and the Republic of the Congo from which cobalt is extracted as a coproduct or byproduct of copper or nickel. The extraction of cobalt from ores and concentrates requires complex and complicated operations in mineral dressing, pyrometallurgy, hydrometallurgy, and electrochemistry.

The United States, the largest consumer of cobalt, used an average of 10 million pounds per year during 1959–63. Industrial consumption in 1963 was 10.5 million pounds. The largest single use of cobalt, 23 percent of the 1963 total, was for high-temperature, high-strength alloys. The use for permanent magnet alloys was second with 22 percent of the total cobalt consumed. Uses in steel amounted to 12 percent of the total.

Bethlehem Cornwall Corp. is the only domestic producer of cobalt concentrate. Pyrites Co., Inc., Wilmington, Del., processes the concentrate into metal, oxide, and hydrate.

Free world production of cobalt in 1963 was 12,700 tons, of which the Republic of the Congo produced 63 percent, and Morocco and Canada produced 12 and 11 percent, respectively. Production exceeds free world demand, but there is substantial demand for the commodity in Communist countries.

The principal problem facing major producers is the disposal of surplus cobalt inventories. Another problem of considerable importance is the high cost of the metal, attributed primarily to the involved and costly processes required and to low yields. The price of $1.50 per pound restricts its use and favors the employment of less expensive substitutes, notably nickel. Among the technological problems are lack of full understanding of the properties of cobalt metal and its role in various alloys, lack of more efficient processing methods and equipment to lower the cost of production, and a great need for more and better manufacturing techniques to expand outlets for cobalt.

BACKGROUND

Cobalt's chemistry and metallurgy date to the middle 16th century when silver-cobalt ores were mined in the Harz Mountains of Germany. These ores contained arsenic which formed poisonous fumes during roasting. The arsenic also caused ulceration of the hands and feet of the miners. They associated their sufferings with gnomes and goblins called Kobolds, and probably the name "cobalt" was derived from this term.

The development of the cobalt industry in Germany is obscure. According to the best accounts, Weidenhammer, in 1520 at Schneeberg, Saxony, was the first to set up a mill; the mill made blue color, known as safflor or saffre. This was a crude cobalt oxide made by crushing and roasting the ore.

Other European countries mined cobalt in later years, but the supply was limited. This small European supply was greatly augmented upon the discovery of large deposits in New Caledonia by Garnier in 1864. These deposits remained the chief cobalt source until about 1903 when the rich silver-cobalt ores of Ontario, Canada, were discovered. Little interest was shown in the Canadian ore until silver was

[1] Commodity specialist.

found in the ore. Consequently, output, as a byproduct of silver refining, increased from 16 tons in 1904 to 1,553 tons in the next 5 years. As Canadian competition increased, the cobalt industry in New Caledonia went into a spiraling decline and ceased cobalt production altogether by 1911.

Mining of cobalt-bearing copper ores began in Katanga Province in the former Belgian Congo about 1910 by Union Minière du Haut-Katanga. About 1920, the firm started to extract cobalt from the ores, and by 1926 it had become the world's leading producer—a position it still retains by a wide margin. Since then, cobalt deposits have been discovered and developed in other parts of Africa, notably Northern Rhodesia and Morocco.

During the late 1800's and early 1900's there were efforts to start a domestic cobalt industry. In 1869 cobalt oxide was produced, probably from raw materials of Canadian origin. For the most part, operations were exceedingly small and did not last long. Consumption of cobalt did not increase substantially until the 1940's, when military needs developed. Then, in fear of being severed from foreign sources, efforts were intensified to develop domestic sources. The Pyrites Co., Inc., Wilmington, Del., started production of cobalt oxide from concentrate, which was supplied by the Bethlehem Cornwall Corp. In 1944, St. Louis Smelting & Refining Co. began commercial production of cobalt from its Fredericktown, Mo., property. Spurred by the war effort, other firms started cobalt production.

After the war, interest in cobalt waned. Consequently, many of the wartime facilities were forced to close. Interest was revived by the Korean conflict. The Calera Mining Co. started and then expanded its production plants in the Blackbird district in Lehmi County, Idaho, at the request of the Federal Government. In return for the expansion the Government in 1951 contracted with the company to purchase initially 6.5 million pounds of cobalt at a fixed premium price. St. Louis Smelting & Refining Co. reopened its cobalt producing facilities in 1955. In 1958, the domestic cobalt industry reached its peak production with 4 million pounds of recoverable cobalt. In 1959, production fell sharply on account of foreign competition and curtailed demand by the Government. Unable to meet foreign competition, Calera Mining Co. closed in mid-1959 after making final deliveries to the Government. St. Louis Smelting & Refining Co. closed in early 1961.

SIZE, ORGANIZATION, AND GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

Most of the world's cobalt is recovered as a minor byproduct of copper or nickel refining. Bethlehem Cornwall Corp. in Pennsylvania is now the sole domestic supplier. Approximately 21 domestic firms, the 3 largest in Cleveland and Cincinnati, Ohio, and Elizabeth, N.J., annually make various products containing about 1 million pounds of cobalt starting with purchased cobalt hydrate, sulfate, scrap, and virgin metal. Chief products are cobalt salts, driers, and related compounds. A list of the companies and their respective products is given in table 1.

World cobalt production is centered in the Republic of the Congo. Union Minière du Haut-Katanga, the sole cobalt producer in the Congo, has mines and concentrating plants near Jadotville and Kolwezi. Its refineries are situated at Jadotville and Luilu. The company also maintains cobalt refining facilities at Oolen, Belgium. Sales of the firm's products in the United States are handled by African Metals Corp., New York, N.Y., and Chicago, Ill.

In Northern Rhodesia cobalt is produced as a byproduct of copper processing by Rhokana Corp. at its electrolytic refinery near Nkana, and by Chibuluma Mines, Ltd., near Ndola. The latter firm produces a matte, which is shipped to Belgium for further refining.

In Canada, cobalt is produced chiefly as a byproduct or coproduct from nickel-copper ores in the Sudbury district, Ontario, and the Lynn Lake area, Manitoba. Some small outputs resulting from precious metal refining still come from the silver-cobalt ores in the Cobalt, Gowganda, and Timiskaming areas. Cobalt-nickel ore is refined at Port Colborne, Ontario, by International Nickel Co. of Canada, Ltd.; at Kristiansand, Norway, by Falconbridge Nickel Mines, Ltd.; and at Fort Saskatchewan, Alberta, by Sherritt Gordon Mines, Ltd. The facilities of the Deloro Smelting & Refining Co., Deloro, Ontario, an appreciable cobalt producer at one time, were closed in March 1961.

In Finland, cobalt is produced from the cupriferous pyrite of the Outokumpu mine of Outokumpu Oy in the eastern part of the country. Sinter produced by roasting pyrite concentrate to remove the sulfur is shipped to Duisburger Kupferhütte at Duisburg, West Germany, for recovery of cobalt.

[1] Code: A, metal; B, oxide; C, hydrate; D, salts; E, driers; F, concentrate; G, scrap.

Cobalt production in Morocco is by La Société Minière de Bou-Azzer et du Graara, which operates a mine and a concentrator south of the Atlas Mountains near Bou-Azzer. The concentrate is shipped to France and Belgium for further processing.

DEFINITION OF TERMS, GRADES, AND SPECIFICATIONS

Cobalt is a silvery-gray metal with a slight bluish tinge, closely resembling nickel in appearance and in many of its properties. It is, however, somewhat harder and more brittle than nickel. Its occurrence is widely distributed and is usually found associated with other metals.

Most of the cobalt used by industry is in the form of metal. Other cobalt forms commonly used are oxides and the salts. Cobalt metal is produced as briquets, granules, squares, broken cathodes, rondelles, fines, and powder. Squares are made by cutting cathodes into square pieces of 1, 2, or 4 inches on a side. Broken cathodes are produced by feeding cathodes through toothed rolls. Rondelles are made by converting compacted pellets of cobalt oxide to metal. Fines are relatively impure form of cobalt produced as an intermediate product in the refining circuit. Cobalt powder is generally made by reducing cobalt oxides with hydrogen and by mechanical grinding of rondelles and other cobalt metal forms. Table 2 gives typical analyses of cobalt metal from leading suppliers.

Cobalt forms three stable oxides—cobaltous oxide (CoO), cobaltic oxide (Co_2O_3), and cobaltosic oxide (Co_3O_4). Only the gray oxide, consisting mainly of cobaltous oxide, and the black oxide, consisting mainly of cobaltosic oxide, are used commercially to any appreciable amount.

The primary producers of salts and related compounds market six cobalt salts—cobalt acetate, carbonate, chloride, nitrate, and sulfate. Many other cobalt salts and compounds are manufactured by producers from cobalt scrap or from one of the aforementioned salts. Nearly all of the cobalt salts used for commercial purposes are in the cobaltous state.

TECHNOLOGY

Geology

Cobalt is about as abundant as lead in the earth's crust. The average content is estimated to be 23 parts per million. Unlike lead, however, it is widely diffused in nature and does not occur in heavy concentrations. For the most part cobalt is associated with ores of copper, nickel, iron, silver, manganese, lead, and zinc.

The three important types of cobalt minerals are sulfides, arsenides, and oxides. The principle sulfide minerals are carrollite (Co_2CuS_4) and linnaeite (Co_3S_4). The principle arsenide minerals are smaltite ($(CoNi)As_2$, safflorite ($(CoFe)As_2$, skutterudite ($(CoNi)As_3$, and cobaltite (CoAsS). The principle oxide minerals are asbolite ($CoO \cdot 2MnO_2 \cdot 4H_2O$), heterogenite ($CoO \cdot 2Co_2O_3 \cdot 6H_2O$), sphaerocobaltite ($CoCO_3$), and erythrite ($3CoO \cdot As_2O_5 \cdot 8H_2O$). Seldom are any of the cobalt minerals found in sufficient quantity to be mined for cobalt alone. Consequently, the amount and concentration of cobalt and the presence of associated metals are factors in making deposits of economic value.

Magmatic differentiation, which produces basic and ultrabasic rocks, seems to concentrate cobalt along with nickel, chromium, and some other metals. The ultrabasic rocks, such as serpentine, do not contain cobalt in commercial quantities. The soil formed from them, however, has concentrations of iron, manganese, nickel, and cobalt after long successive weathering of the rocks, especially under tropical conditions that cause much laterization. The best known examples of such cobalt deposits are the lateritic iron ores. The basic rocks are generally associated with concentrations of iron nickel, and copper sulfides. Most geologists believe that some hydrothermal activity as well as magmatic differentiation is important in the origin of these cobalt deposits. Where the deposits are large, such as at Sudbury, Ontario, some cobalt can be recovered as a byproduct during the recovery of nickel and copper.

Hydrothermal activity has formed by far the largest number of cobalt deposits. Some of the deposits contain sufficient cobalt to be minable as originally formed. Others have been enriched by weathering. There are several types of hydrothermal activity, simplest hydrothermal deposits being veins containing cobaltite in a quartz or calcite gangue. A few such simple veins of cobalt ore have been worked in the Cloncurry district of Australia. For the most part, however, cobalt deposited in this manner is found in relatively small quantities associated primarily with copper deposits. The copper-cobalt ores in the Katanga-Northern Rhodesia districts are examples of such deposits.

Mining

Most cobalt is recoved as a byproduct or coproduct in treating ores of copper and nickel, and descriptions of mining practices as applied to these ores are presented in their respective commodity statements.

Metallurgy

Owing to the variations in cobalt content and type of mineralization of copper-cobalt ores, Union Minière refines cobalt by several distinct methods. Milling and concentrating procedures also depend upon the nature of the ores. The following types of ore are treated separately at the Kolwezi concentrator; copper oxide ore containing small amounts of cobalt, cobalt-copper oxide ore containing approximately equal amounts of the two metals, and mixed ore containing both the oxides and sulfides of copper and cobalt. The copper oxide concentrate is sintered and smelted in an electric-arc furnace at the Panda plant in Jadotville. The four electric furnaces there have a combined annual capacity of 4,400 tons of contained cobalt (*18*).[2] The charges to the electric furnaces are fluxed and reduced by a lime and coal mixture.

The resulting melt is drawn into ladles where it separates into two molten alloys of different density. The bottom layer of so-called red alloy has a composition of 89 percent copper and 4.5 percent cobalt. The top layer, called white alloy, contains approximately 42 percent cobalt, 15 percent copper, and 34 percent iron. The red alloy is later refined to copper at the Panda smelter. During refining, cobalt is slagged off and returned to the electric furnaces. The white alloy is cast into ingots and shipped to the Oolen plant of the Société Générale Metallurgie de Hoboken in Belgium for further processing.

The second type of product, cobalt-copper oxide, from the Kolwezi concentrator is processed in Union Minière's Jadotville-Shituru hydrometallurgical plants. Sulfuric acid is used to leach the metal out of the concentrates. The leached products are then subjected to a series of processes that include: classification to remove the sand, decantation, countercurrent washing, and careful clarification to remove suspended particles. Clarification is accomplished by filtering the solution through finely

[2] Italicized numbers in parentheses refer to items in the list of references at the end of this chapter.

divided sand beds. After adjusting its acidity the filtered solution is subjected to several electrochemical steps to remove copper. The remaining solution contains cobalt, some nickel, zinc, and manganese. The cobalt is then precipitated, separated by filtration, and redissolved in an acid solution and recovered by electrolysis. Resulting cathodes have a composition of 92 to 94 percent cobalt, 1 to 3 percent zinc, and small amounts of nickel, iron, copper, manganese, and sulfur. These cathodes are later melted in electric-arc furnaces and further refined, using special slags and electrodes. The molten purified metal, now over 99.15 percent cobalt, is granulated by pouring it into water.

The mixed ore concentrate, the third product from Kolwezi, contains both the oxides and sulfides of copper and cobalt. The concentrate is first treated in a Fluo-Solid sulfate-roasting furnace, where the sulfides are oxidized to soluble sulfates. The sulfates are repulped with acid solution before they are subjected to the hydrometallurgical and electrometallurgical operations described earlier for the extraction of copper and cobalt. However, a much improved and shorter process for recovery of cobalt is used at the new plant in Luilu. The new process discarded the slow electrolytic copper plating procedures in favor of removing copper with lime. A preliminary nickel removal step also was added to the new process. In this step nickel is removed as a sulfide by the addition of sodium hydrogen sulfide. This operation shortens the circuit by removing the last traces of copper along with the nickel. Zinc is removed as zinc sulfide by the addition of hydrogen sulfide. The solution undergoes further purification and clarification before it is electrolyzed. Cobalt produced by the new process at Luilu is of sufficient purity that it needs no further refining (*14*).

The only domestic producer of cobalt is the Pyrites Co., Inc., Wilmington, Del. The raw material is from magnetite iron ore mined by Bethlehem Cornwall Corp. in Pennsylvania. After magnetic separation a pyrite flotation concentrate is made and sent to the Bethlehem Steel Co. plant at Sparrows Point, Md. The pyrite is roasted in Fluo-Solid reactors and cobalt extracted from the calcined product at Wilmington by percolation leaching. The leaching process requires about 250 hours for the average cycle. Iron, copper, and manganese impurities are removed from the solution by precipitation with sodium carbonate and filtration. The cobalt is then precipitated with sodium carbonate and chlorine, separated from the solution by filtration, and the resulting cobalt cake either calcined to the oxide with about 70 percent cobalt content or reduced to the metal with charcoal. The final metal granules or fines contain 98.0 to 99.0 percent cobalt (*7*). Over 99 percent of the soluble cobalt in the calcine is recovered.

USES

Cobalt has wide applications in many industries. The more important uses are in the manufacture of various steel alloys, permanent magnets, driers, catalysis, and high-temperature, high-strength alloys. The use of cobalt for alloys dates to the turn of the century when Elwood Haynes patented a series of cobalt-chromium alloys, which he named "Stellites". These early alloys were the forerunners of today's high-temperature, high-strength alloys or "superalloys." The special features of these alloys are their high mechanical strength at elevated temperatures and excellent resistance to corrosion by hot gases. The use of superalloys increased rapidly with the development of jet engines, rocket nozzles, and gas turbines, all of which use very hot gases. The cobalt used for these engines and other equipment for outer space accounted for about one-quarter of the total amount consumed.

Another major use of cobalt is in the manufacture of permanent magnets. The first cobalt steel for permanent magnets was developed in 1916 by Honda and Saito. It consisted of 35 percent cobalt, 6 percent chromium, 5 percent tungsten, the balance being iron and trace amounts of other elements. In 1930, Mishima discovered that iron-nickel-aluminum alloys had remarkable permanent magnet properties. A cobalt addition to these alloys was later found to improve the magnetic properties. In 1936, the General Electric Co. announced the development of the first of the aluminum-nickel-cobalt or "Alnico" series of permanent-magnet alloys. Permanent magnets have many uses. Probably the largest single use for Alnico magnets is for loudspeakers. High-fidelity recording and broadcasting of recent years have created a demand for high-quality loudspeakers which may contain Alnico magnets weighing several pounds.

In 1913, Schlesinger showed that the addition of 5 percent cobalt improves the life of high-speed tool steels. Cobalt also raises the melting point of these steels and increases the carbide solubility in austenites. Moreover, the addition of cobalt to an alloy diminishes the tendency to grain growth, retards tempering after quenching, and inhibits the precipitation and coalescence of carbides. For these reasons and others, cobalt has been found particularly useful when the cutting edge of any tool is subjected to high temperature.

Driers are substances used to increase the rate and completeness of the drying of paints, varnishes, lacquers, enamels, and similar materials. Specifically, driers act by catalyzing the polymerization of the oils contained in the paints. All driers are essentially organometallic compounds, chiefly of cobalt, manganese, and lead. Although the cost of cobalt is higher than the other metals used, it is by far the most effective. Because of this superiority, cobalt is used either alone or with other metals.

There are two major categories of cobalt driers, fused and precipitated. The classification is derived from the method of preparation. The fused type is made by adding cobalt hydroxide to rosin at high temperatures. The precipitated type is formed by reacting soluble salts of cobalt with those of the desired organic acids. Fused driers are somewhat variable in composition, and in recent years they have been widely supplanted by precipitated driers on account of their greater efficiency and uniformity. Cobalt resinates and naphthenates are widely used precipitated driers. Other cobalt compounds used for driers in recent years are cobalt octoates, lineolates, and tallates.

In addition to the catalytic activity as a drier, cobalt in form of metal, oxide, or salt is used as a catalyst in many reactions such as hydrogenation, hydration, desulfurization, oxidation, and reduction. Since the oxides are very effective oxidizing agents, they have been a subject of extensive investigation in recent years as possible antismog devices.

A relatively new application for cobalt is in the oxo reaction, which involves the catalytic addition of carbon monoxide and hydrogen to an olefin to form aldehydes, which are reduced to alcohols in the second stage of the reaction.

BYPRODUCTS AND COPRODUCT RELATIONSHIPS

Current world cobalt production is derived entirely from ores of other metals, principally copper and nickel. This relationship is likely to persist, as there are few large deposits containing cobalt as the principal mineral. However, copper, nickel, and gold have been recovered from the cobalt ore mined in Idaho, and nickel and gold are recovered from cobalt ore at the Bou-Azzer mine in Morocco.

ALTERNATE MATERIALS

Although nickel is less efficient in some uses, it can be readily substituted for cobalt in other uses without appreciably altering the desired properties. For example, nickel can be substituted as a binder in cemented carbides and in armor-piercing projectiles. Moreover, a nickel-base alloy, free of or containing only a low cobalt content, can be used as a substitute for some cobalt-base high-temperature alloys.

With some loss of cutting speed and production rate, high-speed tool steels may be substituted for the more expensive tools with high cobalt content.

Alnico magnets can be replaced with bismanol magnet alloy consisting of bismuth, manganese, and powdered iron, or by barium ferrite materials. Bismuth is more expensive than cobalt, however.

Although cobalt driers show the most rapid drying time of all the metal driers, manganese, lead, and iron can be used as substitutes.

SECONDARY SOURCES AND RECOVERY

Very little published material is available concerning the generation, collection, and disposition of secondary cobalt-bearing materials. The average amount of contained cobalt derived from secondary sources during 1959–63 is estimated at about 226,000 pounds per year. Superalloy scrap probably accounts for the bulk of secondary cobalt supply, owing to the fact that current engineering specifications require high-temperature, high-strength material, and components made from such alloys, notably turbine buckets and jet engines, have a relatively brief service life.

Although the permanent magnet industry consumes about the same amount of cobalt annually as does the superalloy industry, the service life of permanent magnets is relatively long. Therefore, magnet scrap probably plays a very minor role in the cobalt scrap supply.

Other possible sources of secondary cobalt are spent catalysts and other nonmetallic alloy scrap. Such materials are much more widely distributed than the metallic types; for this reason it is correspondingly more difficult to collect data concerning them.

RESERVES

The largest recoverable cobalt reserve is in Katanga Province, Republic of the Congo. The primary cobalt ore is found in the so-called Mines Series belonging to the Upper Roan group. The primary ore deposits consist chiefly of bornite, chalcocite, and chalcopyrite, with some carrollite, linnaeite, and pyrite. Ore was originally mined from a number of small enrichments in the oxidized zone in mines near Elizabethville and Jadotville and from

mines in the Western group. These deposits contain 3 to 4 percent cobalt. Now most of the cobalt in this area is extracted from richer sulfide ores. The Union Minière du Haut-Katanga mines reserve is said by the company to contain enough cobalt for at least 80 years of production at an annual rate of 19 million pounds, or about 750,000 tons.

The deposits of Katanga and Northern Rhodesia are geologically in a single mineral district. The ore reserves of Northern Rhodesia have an indicated content of 375,000 tons of cobalt. Elsewhere in Africa, the cobalt-nickel deposits of Bou-Azzer and El Graara, Morocco, are about 105 air-miles southeast of the railroad junction at Marrakech. The Moroccan ore consists mostly of skutterudite, interlaced with some cobaltite, safflorite, niccolite, and several other minerals. Since little development is done ahead of actual mining in this district, ore reserves can only be inferred. Very rough estimates place the reserve at about 800,000 tons with an average of 1.6 percent cobalt content, or a total of about 13,000 tons of metal.

Although the nickel and cobalt deposits in New Caledonia were discovered in 1864, exploitation of these deposits for cobalt did not commence until 20 years later. Cobalt is present in all of the New Caledonian nickel ore in varying amounts. The laterite layer, containing the bulk of the cobalt, has up to 0.5 percent of it, and some rich deposits may contain as much as 5 percent. The average cobalt content of the ore is around 0.2 percent. The Société le Nickel, and firm which controls most of the New Caledonian ore, reported that the known cobalt ore reserve on the firm's property is 220 million tons (*1*).

The immense nickeliferous laterite deposits in Oriente Province, Cuba, probably constitute the largest potential reserve of cobalt in the Western Hemisphere. According to Bureau of Mines estimates, the ore deposits so far prospected in the Levisa Bay, Moa Bay, Toca Bay, and Mayari districts of Oriente Province together with the Plateaus Cajabanes deposit of Pinar del Rio Province contain a total of 370,000 tons of cobalt in ore which averages over 1 percent nickel and 0.1 percent cobalt. In addition, there is a potential reserve of lower grade material with less than 1 percent nickel and about 0.07 percent cobalt containing about 1.2 million tons of cobalt.

There are a number of sources of cobalt in Canada. The Sudbury district, Temiskaming silver-cobalt area, Lynn Lake, and Thompson have the largest deposits. The nickel-copper ore of the Sudbury district and of Thompson, both owned and operated by the International Nickel Co., contain only small amounts of cobalt, variously estimated at 0.06 to 0.1 percent. These deposits constitute the largest known reserve of cobalt on the North American Continent. Cobalt occurs in the ores as a complex mixture of cobalt-nickel-iron arsenides closely associated with pentlandite. The total nickel ore reserve in these two areas at yearend 1963 was about 300 million tons, which would mean a cobalt reserve of about 180,000 to 300,000 tons.

Falconbridge Nickel Mines, Ltd., also has mining operations in the Sudbury district. At yearend 1963, Falconbridge had a proven nickel-copper ore reserve of 27 million tons and an indicated cobalt reserve of about 40,000 tons. The Lynn Lake, Manitoba, nickel-copper ore of Sherritt Gordon Mines, Ltd., contains small amounts of cobalt. Nickel concentrate produced from the ore contains about 12 percent nickel and 0.4 percent cobalt. The reserves of the company total 12 million tons of ore with an average nickel content of 0.94 percent. Assuming the same nickel-cobalt ratio exists in the ore as exists in the concentrate, this would give a cobalt reserve of approximately 3,700 tons.

The United States does not have large minable cobalt reserves. The largest known deposit of high-grade cobalt ore is in the Blackbird district of Lemhi County, Idaho. The former operator of this mine, Calera Mining Co., stated that the measured and indicated reserve contained 7,500 tons of cobalt, where as the inferred reserve is estimated to be about 15 to 20 times larger. The cobalt-bearing lead ores near Fredericktown, Mo., mined at one time by the National Lead Co., constitute another sizable deposit of cobalt ore in the continental United States. Estimated reserves total about 2 to 3 million tons of ore with an average cobalt content of 0.3 percent (*1*).

The cobalt-bearing iron ore deposits of the Bethlehem Cornwall Corp., Cornwall, Pa., the sole domestic cobalt producer, probably constitutes the second largest cobalt reserve in the United States. The large ore bodies contain 40 to 60 percent magnetite and about 3.5 percent pyrite. The pyrite fraction contains 1.5 percent cobalt. Thus, the ore contains an average of about 0.05 percent cobalt (*1*).

SOURCES OF STATISTICAL INFORMATION

The Bureau of Mines obtains monthly data on production and stocks of cobalt from domestic producers; monthly data on production and stocks of cobalt products by forms from all refiners; and monthly data on consumption by forms and end use and on stocks from virtually all consumers. World production data are compiled from State Department dispatches and of-

ficial publications of foreign countries, and figures on foreign trade are obtained from the Bureau of the Census. The Bureau of Mines publishes monthly reports on cobalt and a comprehensive annual report for use by industry and government.

PRODUCTION, CONSUMPTION, AND TRADE

The Republic of the Congo produced 63 percent of the 1963 world cobalt output, and Morocco ranked second, producing 12 percent of the total. The United States consumes approximately 30 to 40 percent of the free world cobalt production.

The Republic of the Congo continued to be the main source of U.S. cobalt imports, providing about one-half of all the cobalt imported in 1963. Belgium, West Germany, and Norway composed the next large group, providing 14, 13, and 10 percent, respectively, of the total. France, Canada, and the remaining countries provided 7, 6, and 3 percent, respectively.

The United States exported a total of about 4,500 tons of cobalt-bearing materials during 1959–63. Scrap, defined as material having at least 5 percent cobalt content, was the chief cobalt-bearing item. Exports of fabricated and semifinished items totaled a little over 250 tons during 1959–63. Shipments to Japan and West Germany were by far the largest.

Cobalt metal and ore continued to enter the United States duty free. Effective July 1, 1963, the duty was reduced on cobalt oxide from 2.7 cents to 1.5 cents per pound, and reduced on the sulfate, from 2 cents to 1.5 cents per pound; the duty on other cobalt salts and compounds, not specially provided for, was reduced from 13.5 percent to 12 percent ad valorem. The duty on cobalt lineolate was increased from 5 cents to 7.25 cents per pound (*16*).

TABLE 3.—*Production of cobalt products in the United States*

[Short tons]

Year	Metal		Oxide		Hydrate		Salts		Driers	
	Gross weight	Cobalt content	Gross weight	Cobalt content	Gross weight	Cobalt content	Gross weight	Cobalt content	Gross weight	Cobalt content
1954–58 (average)	1,987	1,934	259	184	165	86	587	165	4,806	282

1963	(2)	8,050	1,408	778	1,511	210	12,700

[1] Cobalt is also recovered, principally in West Germany, from pyrites produced in Finland, and estimates are included in the world total. Production data for Bulgaria, East Germany, Poland, and U.S.S.R. are not available, and no estimates for these countries are included in the world total. Cobalt concentrates are being stockpiled in Uganda, but exact figures are not available.

[2] Figures withheld to avoid disclosing individual company confidential data; U.S. figures included in world total.

TABLE 5.—*Cobalt consumed in the United States, by uses*

[Short tons of contained cobalt]

Use	1954–58 (average)	1959	1960	1961	1962	1963
Metallic:						
High-speed steel	96	107	78	110	171	202

STRATEGIC CONSIDERATIONS

The major suppliers of cobalt to the United States are the Republic of the Congo, Belgium, and Canada. The refinery in the Republic of the Congo is about 1,200 miles by rail from the Atlantic port of Lobito in Angola. Shipments are made from Lobito to the United States. The principal cobalt refinery in Canada is at Port Colborne, Ontario, about 20 miles from Buffalo, N.Y. Other large refineries supplying cobalt to the United States are in France, Norway, United Kingdom, and West Germany.

PRICES

Since the last change in price on March 1, 1960, the price of cobalt metal granules and regular fines has been $1.50 per pound, f.o.b. carrier, Niagara Falls, N.Y., New York, N.Y., and Chicago, Ill., packed in 500-pound drums. The prices of ceramic-grade cobalt oxides with 70 to 71 and 72.5 to 73.5 percent cobalt content are $1.12 and $1.15 per pound, respectively. Above oxide prices are quoted for 250 pound kegs delivered east of the Mississippi River. For deliveries west of the Mississippi River, 3 cents per pound is added.

TABLE 7.—*Prices per pound of cobalt metal and cobalt oxide in the United States* [1]

Year	Date of change in price	Cobalt metal f.o.b. Niagara Falls or New York, N.Y., Chicago, Ill.	Cobalt oxide, ceramic grade east of Mississippi River (gross weight)
1940–46		$1.50	$1.16

TAXES

Domestic cobalt producers are granted a depletion allowance of 23 percent on income from domestic production and 15 percent on income from foreign production.

In addition to a 15-percent depletion allowance (of salable value of minerals), taxable incomes of operations outside the United States and within the Western Hemisphere are taxed at 14 percentage points below the U.S. corporate income tax rate. With an appropriate rate of 48 percent for domestic operations, the rate for Western Hemisphere trading corporations is approximately 34 percent.

RESEARCH

Bureau efforts in research and development consist of technical and economic feasibility studies of some potential sources of cobalt, and various metallurgical processes for some minerals containing cobalt. Research is also directed toward investigating the chemical and physical behavior of certain compounds and alloys of cobalt. Results of several investigations indicated an improved process of preparing high-quality cobalt and nickel (*12*, *9*, *4*).

The Centre d' Information du Cobalt (Cobalt Information Center), Brussels, Belgium, sponsors many research and development efforts in all phases pertaining to cobalt. Results of one series of investigations dealt with a number of refractory metals and cobalt (*8*). The Center published articles concerning the chief function of cobalt in heat-resisting alloys (*2*) and the oxidation resistance of a number of cobalt-base alloys (*3*). The Center also published two comprehensive, detailed articles on the analytical chemistry of cobalt (*15*).

Despite recently introduced refractory metals and their alloys for high-temperature, high-strength applications, much research continues on the less-expensive cobalt-base superalloys. The Defense Metals Information Center (DMIC), Battelle Memorial Instiute, Columbus, Ohio, recently published a detailed report on various conditions that affect the behavior of cobalt-base superalloys (*17*). DMIC studies also included a compilation of tensile properties of high-strength alloys including cobalt-base superalloys (*5*). Martin Metals Co. produced a high-temperature cobalt-base alloy, designated as SM302. It was developed for use in the first turbine stage of modern turbojet engines. Another cobalt-base alloy, SM322, was developed for use as a turbine-blade material. A new series of cobalt-refractory-metal alloys was announced for advanced space vehicles by the National Aeronautics and Space Administration (NASA). Cobalt-base alloys with refractory metals as the major alloying constituents were found to be especially suited in reducing material loss by evaporation in the ultra-high-vacuum environment of outer space (*10*). A program on the development of coated thin-sheet superalloy components has been in progress at Bell Aerosystems Co. (*13*).

A number of new cobalt products that may find wide applications in the future have been reported. Allegheny Ludlum Steel Corp. developed a new high-strength, precipitation-hardening stainless steel, designated as AM–367. The Forging and Casting Division of Allegheny Ludlum Steel Corp. developed an alloy under the designation of ALX–6. The new alloy was a cobalt-base metal designed primarily for applications that require high resistance to thermal shock and heat checking. Kanthal Corp. announced the development of an iron-chromium-aluminum-cobalt, electrical-resistance alloy, known as Kanthal D. Bethlehem Steel Co. developed an improved hot-work, tool steel for high-temperature operations. The alloy, Chromo-Co, is essentially the same as the firm's Chromo-N, to which 10 percent cobalt has been added. Westinghouse Electric Corp. introduced a new wrought, highly ductile, improved magnetic alloy under the name of Vicalloy. The new alloy, with a 52-percent cobalt content, can be fabricated into various shapes. Russian metallurgists have developed a lower cost, creep-resistant material to replace their designated LK4 alloy. The new alloy has less than 2 percent cobalt compared with 60 percent in the LK4 alloy. Prop-

erties of the new alloy compared favorably with those of the more expensive LK4 alloy.

Sherritt Gordon Mines, Ltd., developed five closely sized grades of very pure cobalt powder for powder-metallurgy applications. Girdler Catalyst Division of the Chemetron Corp. introduced a cobalt catalyst, designated as G–61, which has a high degree of selectivity in reducing certain nitriles to amines.

Several recently developed coating and plating processes promise wide application. Stellite Co., division of Union Carbide Corp., announced the development of four new metallic diffusion coatings. Designated as C–9, C–10, C–11, and C–12, the new alloys are expected to be used on copper and cobalt-base alloys. Lockheed Missiles & Space Co. reportedly developed two new metal plating processes that produce thin ferromagnetic films of almost pure metal, including cobalt on both metallic and nonmetallic bases. Selectrons, Ltd., was said to have developed a modified selective plating technique which may reduce costly rejections of machined parts. Called the Flow-Plating technique, the process appears to have potentially extensive applications. Several metals, particularly cobalt, were said to be specially suited for the new plating technique.

OUTLOOK

Free world cobalt-producing capacity will continue to exceed free world consumption. Consequently, there will be a surplus of cobalt for the foreseeable future. The surplus may be aggravated by the strong demand for copper, which will lead to increased production from cobalt-bearing copper ores.

To bring production and consumption more in balance, new specific uses for cobalt may come from an expanded program of research in new applications and in the development of new products. These new uses may, in turn, result in an increased demand for the metal. In this regard, the outlook for expanding the use of cobalt in permanent magnets, high-temperature, high-strength materials, and other ferrous and nonferrous cobalt alloys is encouraging. Recent research and development efforts have proved successful in improving several methods of extraction of the metal from ores and also in producing cobalt of very high purity. Continued success in these fields eventually will lower the production cost of cobalt to the extent that it may become competitive with less-expensive alternate materials.

The domestic cobalt supply position, however, could be improved greatly by the discovery and development of new and better methods in concentrating, extracting, and producing the metal from domestic low-grade ore and other raw materials. Such technological innovations and improvements would lower the cost of domestic production and provide an incentive to establish a domestic source of cobalt. The domestic supply position could also be enhanced by greater recovery and utilization of cobalt-bearing scrap.

The prospect of finding large deposits of commercial-grade cobalt in the United States is not promising. Hence, for an indefinite period the United States will continue to depend on foreign sources for the greater part of its cobalt needs.

PROBLEMS

High price is one of the major obstacles restricting the use of cobalt in alloy steels in favor of cheaper metals. Nickel, costing about one-half as much as cobalt, is notable among the alternates which impart to alloys chemical and physical properties comparable to those of cobalt alloys. There are other less-expensive substitutes for cobalt which do not alter too much the desired properties of alloys. Furthermore, even where requirements specificially call for cobalt, efforts are made to minimize the amount used. Attributed to the cost of recovery and refinement, the high price of cobalt promises to remain an obstacle to its use.

Although there is some research and development devoted to the expansion of the cobalt market in some particular fields, there is actually no large-scale research and development program to expand cobalt's application; especially, those uses that may require large quantities of the metal. Such a program would also fill a need for basic information pertaining to cobalt. The lack of data on the physical metallurgy of the element, for example, hinders the development of new alloys. Such data are also needed to explain cobalt's precise role in the alloying and other metallurgical processes. A case in point is that of high-temperature, high-strength alloys.

Complete removal of cobalt from engineering materials for atomic and nuclear applications still remains a problem. More efficient recovery of cobalt as a separate product from laterite and serpentine ores and other raw materials

780–887 O—65——17

with low cobalt content is another problem. Much effort could also be devoted to reclaiming high-temperature, high-strength alloy scrap. A simple, quick, and inexpensive field method for identifying and classifying cobalt-bearing scrap material would be of considerable aid.

COLUMBIUM

By Richard F. Stevens, Jr.[1]

ALTHOUGH discovered in 1801, columbium did not find significant commercial application until the 20th century. It was first used as an alloy constituent in steels, and this continues to be the metals major volume usage. Pure columbium metal and nonferrous columbium-base alloys currently are used in nuclear reactors and in heat- and corrosion-resistant applications in jet engines, missiles, supersonic aircraft, and space capsules. Magnets of superconducting columbium compounds are being used in attempts to control fusion reactions.

Although no domestic production of columbium ores or concentrates was reported from 1960 through 1963, the United States has been the world's largest consumer of columbium ores and the largest producer and consumer of columbium metal and ferrocolumbium. The demand for columbium metal and ferrocolumbium is expected to increase in response to the growing steel industry and the demand for materials possessing elevated-temperature strength properties for use in space- and nuclear-age technology. Continued research will be required to develop less costly processes for all phases of columbium metallurgy in order to meet the purity and cost specifications expected for advanced high-temperature uses.

Several million tons of columbium have been reported in low-grade complex oxide minerals and in titanium ores. Economic methods for recovering the columbium in these ores will have to be developed if they are to be utilized to meet expected demands.

BACKGROUND

During the 1930's columbium came into use as a steel-alloying element in the form of ferrocolumbium and as a carbide in high-speed cutting tools.

Ore shortages and increased demand for ferrocolumbium during World War II resulted in temporary allocation controls. By the end of World War II, new nonferrous columbium-bearing alloys were being used in jet engines. Shortages were again encountered during the Korean war, and in 1952 a Government-guaranteed purchase program was instituted to encourage increased production of columbium-tantalum concentrates. The desired results were achieved, and new low-grade deposits of columbium minerals were found. Termination of Government purchases of foreign columbium concentrate in May 1955 and of domestic columbite in December 1958 resulted in lower ore prices, followed by reduced production of concentrate. Industrial demand, however, began to increase for the mineral as new firms began production of the metal. This was encouraged by orders for columbium metal and columbium-base alloys to be used in nuclear-reactor research, and by the promise of columbium-bearing high-temperature alloys for jet engines, gas turbines, high-speed aircraft, and missiles.

SIZE AND GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

Columbium mining has been predominantly a foreign industry. Nigeria, Malaysia, Congo (Leopoldville), Norway, Canada, and Brazil are the principal ore-producing countries. Domestic mine output until 1956 consisted of intermittent and highly variable production from many pegmatite deposits in South Dakota, Colorado, New Mexico, Maine, New Hampshire, and North Carolina, with minor production

[1] Commodity specialist.

from a few other States. In 1956, production started from euxenite-columbite-monazite placer deposit in Bear Valley, Idaho, and continued into 1959. Since 1960 there has been no domestic production of columbium concentrate.

The present refinery capacity in the United States is estimated to be more than 300 tons of columbium. This is several times the installed capacity of the rest of the free world.

Columbium metal, compounds, or alloys were produced during 1963 by E. I. Du Pont de Nemours & Co., Inc., Newport, Del., and Baltimore, Md.; Fansteel Metallurgical Corp., North Chicago, Ill., and Muskogee, Okla.; Kawecki Chemical Co., Boyertown, Pa.; Kennametal Inc. Latrobe, Pa.; Stauffer Chemical Co., Richmond, Calif.; Union Carbide Metals Co., Niagara Falls, N.Y.; Union Carbide Stellite Co., Kokomo, Ind.; and Wah Chang Corp., Albany, Oreg.

Some foreign firms reported as producing columbium metal, compounds, or alloys follow: Canada—St. Lawrence Columbium and Metals Corp.; England—Murex Ltd., Blackwell's Metallurgical Works Ltd., Minworth Metals, Ltd., and London and Scandinavian Metallurgical Co., Ltd.; Belgium—Fansteel-Hoboken, S.A.; France—Fabriques de Produits Chimiques de Thann et Mulhouse S.A., and Société d'Électrométallurgie d'Ugine; Germany—Herman C. Stark A.G., Heraeus Quarzschmelze, and Gesellschaft für Électrométallurgie; Austria—Metallwerke Plansee; Switzerland—Société des Produits Pharmaceutiques Ciba; Finland—Kovametalli Oy; Italy—S.P.A. Leghe è Metalli; Japan—Showa Denko K.K., Tokyo Electrolysis Co., Ltd., and Japan Vacuum Engineering Co., Ltd.

DEFINITION OF TERMS, GRADES, AND SPECIFICATIONS

Columbium is a silver-gray, lustrous metal about as hard as copper. It is characterized by high melting point, resistance to corrosion, and ease of fabrication. At elevated temperatures the metal is an excellent interstitial absorber of common gases, but the massive metal rapidly becomes coated with a nonvolatile oxide which retards deeper penetration. It is a relatively good conductor of heat and electricity and an excellent thermionic emitter of electrons in vacuum tubes. It has about the same density as steel and a relatively low thermal-neutron-capture cross section of 1.1 barns.

The name "columbium" was proposed in 1801 when Hatchett, an English chemist, discovered a new metallic oxide in a mineral from the United States (Columbia). In honor of the land of its origin, he named the new element columbium and the mineral which contained it columbite. The following year, the Swedish chemist, Ekeberg, isolated what he thought was a new element and named it tantalum, after Tantalus a minor god of Greek mythology, because of the way it had tantalizingly kept its identity from his grasp for many years. In 1844 Rose concluded that Ekeberg's material had really been a mixture of two elements and named the second niobium in honor of Niobe, the daughter of Tantalus. In 1866 Marignac determined that Hatchett's columbium and Rose's niobium were the same, but to this day the dual nomenclature for the element has continued.

Columbite is marketed on the basis of a minimum of 65 percent combined columbium and tantalum pentoxides in specified ratios of Cb_2O_5 to Ta_2O_5, generally 10 to 1 or 8½ to 1.

Columbium is sold in many grades, ranging from a technical-grade metal of 95 percent purity to nuclear-grade metal more than 99.9 percent pure.

Ferrocolumbium usually is sold on a basis of 50 to 60 percent columbium, maximum 0.40 carbon, and maximum 8 percent silicon. Material containing about 70 percent columbium also is marketed.

Ferrotantalum-columbium contains at least 20 percent tantalum and 40 percent columbium.

National stockpile purchase specifications for columbite are based on three grades. Grade A requires 65 percent combined pentoxides with a minimum ratio of Cb_2O_5 to Ta_2O_5 of 10 to 1. Grade I requires 60 percent combined pentoxides with a minimum ratio of Cb_2O_5 to Ta_2O_5 of 8½ to 1. Grade II requires 55 percent combined pentoxides with a minimum ratio of Cb_2O_5 to Ta_2O_5 of 1 to 1.

TECHNOLOGY

Geology

The percentage of columbium in the crust of the earth has been estimated at 0.0024 percent (*17*).[2] The principal columbium minerals are pyrochlore, fergusonite series, tapiolite-mossite series, columbite-tantalite series, euxenite-polycrase series, eschynite-priorite series, betafite series, samarskite, and columbian perovskite.

Originally the major source of columbium was from minerals of the columbite-tantalite series recovered from pegmatite deposits and residual and placer deposits derived from the weathering of pegmatites or granites. Currently, however, the major source of columbium is the pyrochlore minerals which occur associ-

[2] Italicized numbers in parentheses refer to items in the list of references at the end of this chapter.

ated with alkalic rocks in pegmatites, nepheline syenite, various alkalic dike rocks, carbonatites associated with alkalic intrusives, extrusive alkalic rocks, greisen, and in decomposed products of these rocks. Pyrochlore is generally brown or black in color and has a specific gravity of 4.2.

Many carbonatite bodies are reported to contain columbium, titanium, zirconium, rare-earth metals, barium, strontium, uranium, magnetite, phosphate, vermiculite and agricultural-grade limestone.

Columbium minerals occasionally are associated with cassiterite or gold in veins. Characteristic geochemical associations are most often with tantalum, rare-earth elements, titanium, zirconium, and tin (*17*).

Mining

Depending upon local labor and power supply and the geologic nature of the deposit, mining methods extend from native hand labor to giant dredges and highly mechanized open pit mining operations. Underground mining is restricted to relatively shallow inclines and shafts which have followed rich ore shoots beyond the practical limit of open cut mining techniques.

Metallurgy

Concentration

Columbium-tantalum concentrate is produced by hand sorting, by various combinations of gravity, magnetic, and electrostatic separation, or by chemical means. Flotation methods, used only in Norway at present, may be useful in future treatment of pyrochlore ores.

Extraction and Separation of Compounds and Reduction to Metal

Columbium and tantalum are very similar chemically, and complete separation of the two is very difficult. The classical method for extracting columbium and tantalum from their ores is by fusion with hot sodium hydroxide followed by leaching with water and with hydrochloric acid to remove impurities. The columbium-tantalum residue is dissolved in anhydrous hydrogen fluoride, and potassium hydroxide is added. Upon cooling, potassium-tantalum fluoride precipitates, leaving more soluble potassium-columbium oxyfluoride in solution. The columbium solution is then passed through an involved series of steps including precipitation, solution, fractional crystallization, washing, and calcining to produce columbium pentoxide. Solvent extraction methods, perfected by the Bureau of Mines, are also used commercially to separate columbium and tantalum oxides. The solvent extraction system, hydrofluoric acid-sulfuric acid-methyl isobutyl ketone, will yield more than 90 percent of the contained columbium and tantalum values, free of each other and all metallic impurities, regardless of the columbium-tantalum ratio in the starting material. Chlorination of ferrocolumbium with subsequent separation of pure columbium chloride by fractional distillation is a third technique.

Euxenite from Idaho was processed by Mallinckrodt Chemical Works, St. Louis, Mo. The concentrate was digested with hot sodium hydroxide, washed, leached with hydrochloric acid, and filtered. The residue contained columbium, tantalum, and some impurities, while the filtrate contained uranium, thorium, rare-earth elements, and iron. By dissolving the columbium-tantalum residue and reprecipitating it several times under close pH control, the columbium-tantalum oxides were separated from impurities.

Columbium metal is usually prepared from briquets made from the pentoxide in a stoichiometric ratio with columbium carbide. The briquets are heated in a vacuum to above 1,600° C, the carbon and oxygen forming carbon monoxide. The remaining columbium metal is fed to a ball mill and ground to a fine powder. Other reduction methods include bomb reduction of the oxide with calcium and iodine and Kroll process reduction of columbium chloride.

Columbium powder is pressed into porous bars and sintered in a high-vacuum furnace in one method of producing ingot. The bars are heated by passing an electric current through them for several hours. Other methods of producing pure consolidated ingot include consumable-electrode vacuum arc melting, zone melting, and electron-bombardment melting. This last technique permits a remarkable degree of purification and will probably be of increasing importance. Levitation melting is used experimentally.

Use Technology

Columbium is added to steel in the form of ferrocolumbium or ferrotantalum-columbium, both of which are less expensive than the pure metal. The ferroalloy may be manufactured in two ways. In the electric furnace method, columbite ore, silicon or silicon alloys, and fluxing agents form the furnace charge. Both slag and metal are tapped at a temperature above 1,600° C. In the aluminothermic method, the ore must be carefully dressed before smelting to eliminate associated minerals that would be deleterious to the final product. The charge consists of the refined concentrate, aluminum powder, and oxidizing agents such as sodium

chlorate and barium peroxide. The reaction is started by igniting a small quantity of aluminum powder and barium peroxide on top of the charge.

In preparing columbium carbides, the metal powder may be carburized directly by mixing with a stoichiometric quantity of carbon and heating slowly to 2,000° C in hydrogen or in a vacuum, by firing a mixture of powdered metal and carbon in a closed graphite tube in a hydrogen atmosphere at about 1,600° C, or directly from ore or oxides by smelting with carbon and various molten metallic solvents, such as aluminum, and then purifying the resultant carbide crystals by acid treatment of the regulus to remove aluminum and aluminum carbide. Columbium oxides also will react with lampblack at about 1,900° C in an inert atmosphere to form carbides. A German method sinters a mixture of iron, tantalum, and columbium powders with carbon. The sinter is powdered, leached with hydrochloric acid, heated to 1,600° C for 2 hours, and again powdered and leached with dilute hydrochloric and hydrofluoric acid to remove final traces of iron.

Columbium fabrication and working are affected by several characteristics of the metal. Since the metal, when hot, readily absorbs gases that cause embrittlement, all forming, stamping, and drawing are done cold or in an inert atmosphere. The metal also seizes and tears easily so that caution must be used during machining. Columbium is comparable with mild steel in its ability to be drawn, stamped, or formed. Columbium work hardens at a much slower rate than most other metals, and reduction in thickness of 60 percent or more, without an intermediate anneal, is standard practice. Columbium can be welded to a number of other metals by either resistance welding or inert-gas arc welding. For welding the metal to itself, however, arc welding is used exclusively. Oxygen and other common gases must be excluded from the weld zone. Because of its tendency to oxidize at elevated temperatures, columbium must be protected during arc welding with an inert atmosphere of helium or argon.

USES

Ferrocolumbium (50–70 percent columbium) or ferrotantalum-columbium (approximately 40 percent columbium and 20 percent tantalum) is added to some austenitic stainless steels. About 1 percent columbium and tantalum will act as a carbide stabilizer. Columbium also increases the strength and impact properties of low-carbon and low-alloy steel. It is also a useful constituent with aluminum in the nitriding of steels. Uses of columbium- or tantalum-bearing steel include aircraft engine exhaust systems, welded equipment for the chemical, oil, and food industries, heavy construction equipment, and aircraft landing gear. Examples of columbium-bearing steels are type 347, 19–9WX, Croloy 15–15N, and GLX–W. Columbium-bearing electrodes are used for welding stabilized stainless steels.

Columbium is added to special steels and nonferrous "superalloys" in quantities up to 5 percent for use at elevated temperatures. Examples of such alloys are S–816, Inconel–X, MST–821, and Gamma-Cb. New columbium-base alloys have recently been marketed, such as Du Pont 80–Cb, 10–Mo, 10–Ti, Fansteel 80 and 82, and General Electric F–48 and F–50. Jet engines, automotive gas turbines, research programs on nuclear- and rocket-powered aircraft, and missiles all use such alloys.

British Standard aluminum casting alloy LM 7 specifies 0.05 to 0.30 percent of columbium and titanium. Columbium acts as a grain refiner in these alloys for use in cylinder blocks and crank cases.

Columbium is sometimes used as a getter and electron emitter in electronic tubes. In addition to ability to absorb and hold the residual gases when heated, the metal offers a high melting point, ease of fabrication, and efficient thermionic electron emission. A new type of miniature electronic valve, the cryotron, consists of a tiny strip of tantalum around which a fine columbium wire is wrapped. The combination becomes superconductive in a bath of liquid helium at about −270° C. Such a component has a considerably lower power consumption than a thermionic valve, and a hundred such devices will fit into a thimble. They offer revolutionary possibilities for computer design and great improvement in radar devices.

Columbium metal is used as a fuel-alloying element in the Experimental Boiling Water Reactor, Argonne, Ill., and as fuel cladding in the reactor at Dounreay, Scotland. Columbium, with a neutron-absorption cross section of 1.1 barns, also withstands the corrosive action of coolants and stabilizes the proportions of the fuel element. When used as a fuel-alloying element, columbium prevents violent reaction between the fuel and leaking coolant. Columbium 95 radioisotope is produced at Oak Ridge National Laboratory for use as a radioactive tracer.

Columbium carbide can be used separately or blended with tungsten and tantalum carbides and cemented with cobalt metal. Such carbides are used in hot-forging dies, cutting tools, jet engine turbine blades, valves, valve

seals, and valve guides, and for coating graphite rocket nozzles.

Columbium oxide was used during World War II as a catalyst in the production of butadiene from alcohol. The process has since been replaced by a more economical one using petroleum feedstocks that do not require the use of columbium-bearing catalysts.

BYPRODUCTS AND COPRODUCT RELATIONSHIPS

Columbium in ore is usually a coproduct with tantalum and in some cases is associated with other valuable minerals such as cassiterite, mica, feldspar, beryl, and spodumene. In more intimate association, columbium and tantalum may share a crystal lattice with other valuable elements such as rare-earth metals, tin, uranium, zirconium, titanium, thorium, phosphorus, and calcium. The particular suite of valuable constituents in a given deposit often determines whether or not it can be worked profitably. Outstanding examples are the cassiterite-columbite operations in Nigeria and the euxenite-columbite-monazite ore dredged in Idaho.

Tin smelter slags and tin mine tailings are sources of columbium-tantalum. Although current practice is to separate most of the columbium-tantalum concentrates by magnetic means at the mine while the remainder of the columbite-tantalite reports with the tin concentrate, some tailing piles contain significant quantities of columbium-tantalum minerals. Tin smelter slags may contain up to 20 percent combined columbium and tantalum pentoxides.

Bauxite deposits formed from decomposition of columbium-bearing syenites, such as those in Arkansas, contain columbium-bearing minerals. Titanium plants using columbium-bearing titanium minerals as a raw material are also a potential source of columbium.

ALTERNATE MATERIALS

Acceptable but less satisfactory substitutes, such as vanadium, are available for some uses of columbium. In some stainless steels, low-carbon or titanium-stabilized steels vanadium may provide satisfactory service. For high-temperature applications, several materials are possible substitutes, including molybdenum, vanadium, or tungsten alloys, ceramics, ceramic coatings and other claddings upon less-heat-resistant alloys, and glass-reinforced plastics. In nuclear reactors columbium for fuel-element cladding is an alternate choice for materials such as zirconium, aluminum, vanadium, and stainless steel. Tantalum, zirconium, titanium, and misch metal are preferred to columbium as a getter in vacuum tubes.

Certain alloys and compounds of technetium, molybdenum, vanadium, tin, and gadolinium also have superconducting properties and could be substituted for columbium alloys and compounds to control nuclear fusion reactions.

SECONDARY SOURCES

Data are not collected on utilization of columbium scrap. However, when all scrap sources, including columbium-bearing steel scrap are considered, the quantity of columbium reclaimed for further use is important.

RESERVES AND RESOURCES

By 1960 the total cataloged columbium resource of the free world was reported to be more than 9 million tons of Cb_2O_5 (*4*). The resources occur primarily in pyrochlore, pegmatite, and placer deposits and were distributed in the following way: North America, 1.26 million tons; South America, 6.36 million tons; Europe, 42,250 tons; Africa, 1.39 million tons; and Oceania, 1,000 tons.

The total measured and inferred resource of columbium in the United States was reported to be 180,400 tons of low-grade columbium pentoxide in 1960. The reported grades ranged from 0.004 to 0.15 percent of contained oxides in the ore, too low for economical recovery using present methods of extraction.

Prior to 1955, domestic columbite-tantalite minerals were obtained entirely as a byproduct from pegmatites. Because of the highly variable columbium content of pegmatite deposits the reserves can only be inferred on the basis of the estimated volume of the deposits and the past history of columbium production from these and similar ores. The placer deposits of Idaho and the unconsolidated sediments in the Western States have an inferred reserve of 11,000 tons of Cb_2O_5. Additional resources of columbium exist in the pyrochlore deposits of Colorado. The titanium and bauxite deposits of Arkansas contain columbium in concentrations ranging from 0.05 to 0.15 percent Cb_2O_5. The red mud and black sand waste products of Arkansas alumina plants contain about 0.13 percent of columbium pentoxide which could serve as an emergency source of domestic columbium.

The largest known primary columbite resource occurs in weathered columbite-bearing granite in Nigeria. Columbium also is found in large placer and pegmatite deposits in Africa, Asia, and South America. Some tin tailings and smelter slags also contain columbium in significant quantities. The large low-grade

pyrochlore deposits of Germany, Norway, Brazil, East Africa, and Canada have been extensively explored; most of the measured resources of columbium are in these deposits.

SOURCES OF STATISTICAL INFORMATION

Data on the domestic production and consumption of columbium concentrate and production of the metal, alloys, and compounds are obtained by the Bureau of Mines through industry canvasses. Statistical data on imports and exports of concentrates and products are obtained from the Bureau of the Census, U.S. Department of Commerce. Data on world production of concentrates are compiled by the Bureau of Mines from information supplied by foreign service officers, from official publications of the Departments of Mines of foreign countries, and from other sources. Statistics on imports of columbium-tantalum-bearing tin slags or on the columbium-tantalum pentoxide content of imported concentrates are not obtained, nor are data on secondary recovery of the metals, or on consumption and use of the secondary recovered metals. There is a growing need for more complete information on consumption.

TABLE 1.—*Salient statistics of columbium*

[Pounds]

	1954–58 (average)	1959	1960	1961	1962	1963
United States:						
Columbium-tantalum concentrate shipped from mines [1]	212, 244	189, 263	----------	----------	----------	----------
Imports:						
Columbium-mineral concentrate	5, 604, 171	3, 395, 816	5, 051, 800	2, 777, 700	5, 050, 888	5, 909, 512
Columbium metal and columbium-bearing alloys	[2] 3, 602	[3] 1, 562	[3] 5, 123	2, 139	2, 875	1, 414
Exports:						
Columbium ore and concentrate	26, 181	15, 060	155, 399	56, 487	21, 330	46, 887
Columbium metal and columbium-bearing alloys	104	[4] 6, 495	[4] 21, 469	[4] 28, 930	[4] 34, 761	[4] 58, 666
Industrial consumption:						
Metal contained in raw materials consumed	820, 000	1, 190, 000	1, 538, 000	1, 738, 000	2, 844, 000	2, 054, 000
Ferrocolumbium and ferrotantalum-columbium	[5] 455, 968	565, 418	721, 487	1, 052, 181	1, 397, 638	1, 345, 789
Industrial production:						
Metal	(6)	(6)	(6)	252, 000	128, 000	104, 000
Ferrocolumbium and ferrotantalum-columbium	[7] 558, 000	709, 947	847, 968	1, 156, 051	1, 573, 915	1, 575, 943
World: Production of columbium-tantalum concentrates [8]	7, 990, 000	6, 040, 000	7, 020, 000	7, 540, 000	9, 210, 000	10, 660, 000

[1] 1956–58 data are for columbite-tantalite concentrate plus columbium-tantalum oxide content of euxenite concentrate.
[2] Average of 1956–58 only.
[3] Columbium and tantalum metal and alloys. Separate statistics for columbium are not available.
[4] Columbium and tantalum metal and alloys in crude and semifabricated forms and scrap. Separate statistics for columbium are not available.
[5] Data for 1958 only; data for previous years are unavailable.
[6] Figure withheld to avoid disclosing individual company confidential data.
[7] Average of 1957–58 only.
[8] Separate statistics for columbium ore are not available. Does not include tin slags.

PRODUCTION, CONSUMPTION, AND TRADE

Since 1940, the United States has been the world's leading consumer of columbium ores and producer of columbium-bearing products.

In 1963 the United States imported all of its columbite supply, and 68 percent of the total originated in the Eastern Hemisphere and South America.

Columium ore and concentrate, and columbium-tantalum-bearing tin slags are imported duty free. Duties on columbium-bearing metal scrap have been suspended by Public Law 869 (1950) as amended and extended. Columbian metal and alloys are dutiable at 10 percent, ad valorem, effective August 31, 1963, under the "Tariff Schedules of the United States, Annotated (1963)." For Communist nations the Statutory Rate of Duty of 25 percent, ad valorem, remains in force.

STRATEGIC CONSIDERATIONS

The quantities of columbium concentrates, compounds, and alloys stockpiled by the Government are considered to be satisfactory for

all potential emergency requirements. Foreign purchases consequently have been terminated, and no further domestic contracts are planned. Material is still acquired by barter. On June 30, 1964, inventories of stockpile-grade columbium totaled 14.2 million pounds, of which 6.0 was in the national (strategic) stockpile, 7.9 in Defense Production Act stocks, and 0.3 in the supplemental stockpile.

Domestic industry is dispersed enough to present no strategic problems.

Because of the dependence upon Eastern Hemisphere supplies, it was necessary during the peak of World War II submarine attacks to airlift high-grade ore to the United States for military uses.

Since then, however, several million tons of columbium-bearing pyrochlore have been found in Canada and Brazil and lesser quantities in the United States. In 1963, 32 percent of the U.S. columbite supply was imported from Canada. Western North American black sands, particularly in Idaho, contain large quantities of euxenite and columbite and constitute an important strategic reserve. Low-grade columbium resources are known in the titanium and aluminum ores of Arkansas, which offer additional emergency sources of columbium.

GOVERNMENT PROGRAMS

All stockpile objectives have been exceeded. The stockpile totals are supplmented by more than 15 million pounds of contained pentoxides in concentrates bought under a special Government purchase program and by columbium oxide and ferrocolumbium purchased under individual contracts.

The increased demand during World War II for ferrocolumbium and dependence on waterborne imports resulted in control of columbite imports and allocation controls on ferrocolumbium. During the Korean action, controls were again applied on the production, distribution, and use of ferrocolumbium and ferrotantalum-columbium. Controls on the purchase and use of columbium are not now in effect.

Government support for columbium continues to be offered by the Office of Minerals Exploration (OME) which encourages exploration for columbium ores in the United States by providing loans for 50 percent of approved costs of exploration.

Financial support of columbium research is supplied by various Government agencies (Navy, Air Force, NASA, AEC) to universities, industries, and private research organizations.

PRICES

During 1963, prices for columbite ore, c.i.f. U.S. ports, were quoted by E&MJ Metal and Mineral Markets at \$0.90 to \$1.00 per pound of contained pentoxides for material having a Cb_2O_5 to Ta_2O_5 ratio of 10 : 1, and \$0.80 to \$0.90 for that having an 8.5 : 1 ratio.

In 1963, columbium metal, reported by E&MJ Metal and Mineral Markets was quoted at \$36 to \$50 per pound depending upon form (roundels, electrode segments, and ingot) and quantity.

The price of ferrocolumbium during most of 1963 was \$3.45 per pound of contained columbium (50 to 60 percent columbium). In mid-December the price dropped to \$3.00 per pound. The price of ferrotantalum-columbium was \$3.05 per pound of contained columbium plus tantalum.

TAXES

Depletion allowance is 23 percent for domestic producers of columbium ore, and 15 percent for U.S. producers with production in foreign countries.

TRANSPORTATION AND STORAGE

Transportation and storage of columbium ores or concentrates present no special problems. For stockpiling, they are packed in 55-gallon galvanized steel drums, but commercial shipments also are made in cotton or burlap bags and wooden kegs.

Columbium powder and pellets are usually packed in polyethylene bags in steel drums to prevent contamination by dust and iron.

Columbium fluoride is soluble in water and will hydrolyze to evolve hydrofluoric acid. The containers must be kept dry at all times to prevent production of the highly corrosive acid fumes. Satisfactory containers include rubber-lined drums or coated fiber containers. The storage area for the fluoride should be dry, cool, ventilated, and fireproof without a sprinkler system.

RESEARCH

Research on columbium technology has greatly accelerated in the past 15 years (*15*). Industry, private research institutions, universities, and Government agencies have published information on the ore resources, properties, perparation, and uses of the metals, their alloys, and their compounds.

The Bureau of Mines has been evaluating resources (*13*) and has been studying analytical procedures (*6, 18*), extraction, separation, reduction, and purification of the metal (*5, 7, 9, 14*), and development of alloys (*1, 2, 20*) in re-

cent years. Facets of Bureau work have included sampling and evaluation of the Bear Valley Placers in Idaho and other northwestern placers, determination of columbium reserves in Arkansas and the development of methods to concentrate the minerals and extract the metal, benefication studies of columbium-tantalum bearing minerals in alluvial black-sand deposits in the Northwest, extraction of columbium and tantalum from low-grade ores, including euxenite and tin slags, separation by solvent extraction, anhydrous separation, reduction techniques, and preparation of high-purity metals and alloys.

Industry and institutions have numerous research programs under way. These include new uses, high-purity metal production, improved high-temperature alloys, processes for concentrating pyrochlore-type ores, improved impact- and corrosion-resistant steels, and other basic problems.

Important recent results of research have included new commercial separation methods, new techniques to produce ingot by electron bombardment, and improved alloys.

In addition to studies being conducted by the Bureau of Mines, research on the development of columbium-base alloys for use at elevated temperatures is currently being sponsored by the U.S. Atomic Energy Commission (AEC), the National Aeronautics and Space Administration (NASA), and the U.S. Department of Defense (*10, 12, 22*). Studies sponsored by the Navy, Air Force, and NASA are investigating protective coatings which will prevent or retard oxidation at the elevated temperatures encountered by space and aeronautical structures (*3, 8, 11, 21, 23*).

OUTLOOK

Despite competition between columbium and substitute materials, the consumption of columbium as indicated by current trends should continue to grow. Columbium consumed as an alloying material in steel will represent the largest volume usage. Because of its excellent corrosion-resistant properties, columbium will be used in increasing amounts in high-temperature stainless steels and in oil and gas transmission pipes. Columbium steels also will be used in the chemical-processing industry, construction machinery, and aircraft landing gear because of the corrosion-, heat-, and impact-resistant properties of columbium alloys.

Columbium metal and nonferrous columbium-base alloys having exceptional high-temperature properties are finding new and specialized applications in nuclear power reactors, experimental breeder reactors, gas turbines, jet engines, and missile and aircraft structures. The demand for columbium in these specialized areas should accelerate rapidly and represent the largest single area of growth. Columbium-base alloys, which resist both the elevated temperatures encountered during reentry and the low temperatures in outer space, are being considered as structural materials for space capsules.

Because of their superconducting characteristics at cryogenic temperatures certain columbium-base alloys will develop an additional economically significant market. Superconducting alloys and compounds of columbium probably will be used to control and contain nuclear fusion reactions. The extremely high temperatures of fusion reactions exceed the melting points of all known materials and must be contained by a magnetic force; superconducting columbium alloys produce a containing magnetic field without requiring the continued addition of electrical energy.

Although low-grade domestic sources of columbium have been discovered in both pyrochlore and columbite-tantalite ore deposits, the domestic industry will continue to draw upon imports for most of its supply of raw material.

PROBLEMS

The major potential problem facing the domestic columbium industry has been that of supply. However, with the development of pyrochlore deposits in Canada the United States will not be as dependent upon less reliable sources as in previous years.

Because of the complex nature of columbium-bearing ores, efficient separation and recovery are both expensive and difficult. The development of economical extraction processes is another major problem facing the columbium industry. Recent research has led to the use of such complex practices as fractional distillation, solvent extraction, and fractional crystallization to separate columbium from low-grade columbium-tantalum ores. Although scientifically practical, these operations involve costly equipment and reagents and are too expensive to be used commercially. When current sources of economic supply become depleted and the price justifies their use, some of the newer extraction techniques will be utilized.

COPPER

By F. L. Wideman [1]

COPPER has been essential to mankind's existence from prehistoric times to the present. Its value from antiquity until the 19th century was related to its malleability and ease of working, its attractive colors in alloys and unalloyed forms, its durability and corrosion resistance, and its availability. The first uses were for utensils, tools, and weapons and later uses included pipe, statuary, objects of art, and building and architectural uses where permanence and beauty were essential qualifications. These uses of copper have grown tremendously and its ability to form numerous alloys has led to a myriad of applications from minature eyelets to huge bronze battleship propellers. The 19th century marked the beginning of an epoch of copper's greatest use in the generation and transmission of electrical energy. The conductivity of copper was fundamental to the spectacular growth of the electrical industry and all associated industries relying on electricity for light, power, and heat. More than half the copper produced is used for the transmission of electricity.

The United States has been the largest copper-producing nation in the world since 1883, except for 1934 when economic conditions adversely affected domestic production and Chile ranked first. Ore and waste produced at copper mines in the United States in 1960–63 was more than the total materials handled at mines producing ore of any other metal. Four large companies mine, smelt, and refine a large percentage of the domestic production; and plants associated with these companies account for more than half the output of fabricated products.

Outside the United States, two American companies operate the large mines of Chile and one of these companies operates the largest mine in Peru. Output of Northern Rhodesia is derived from six mines operated by two companies and total production from the Republic of the Congo is derived from several mines controlled by one company. A large percentage of the production from Canada came from six large mines in Quebec and Ontario and two mines in Manitoba-Saskatchewan.

There are many copper minerals but only a few are important commercially. Copper ores occur in many types of deposits in various kinds of host rocks. Porphyry deposits, however, contain most of the world's reserves and are adaptable to mining by open-pit or block-caving methods. Cut and fill, shrinkage stoping, and room and pillar are large-scale methods used in underground mining. Copper metal is recovered from its sulfide ores by concentrating, smelting, and refining and by leaching followed by precipitation or electrowinning for oxide ores. Recently, encouraging results have been obtained in treating refractory ores such as the silicates. The method used to refine copper depends to a large extent on the nature of the byproducts and impurities present. Blister copper containing precious metals, tellurium, and selenium is electrolytically refined and copper containing volatile impurities can be fire refined. The final refined product is almost pure (99.9+ percent) and is cast in several refinery shapes which are used to produce fabricated and semifabricated copper and copper-base alloy products. Metals recovered as byproducts from the treatment of copper ores include iron, lead, zinc, nickel, cobalt, gold, silver, platinum-group metals, selenium, tellurium, and arsenic. Sulfur is also recovered in byproduct sulfuric acid.

Aluminum serves as an alternate metal for copper and its alloys in many electrical, structural, and decorative applications. Copper-clad metals, stainless steel, and plastics also have replaced copper in some uses.

The copper industry has been able to meet an ever-increasing demand by the discovery of new resources and advances in technologies which have converted uneconomic and low-grade material into ore. The world reserve, in terms of metal copper, was estimated to be 212 million tons in 1960, almost double the reserve in 1935. Six principal areas contain 85 percent of the measured and indicated reserve of the world.

[1] Commodity specialist.

In order of the magnitude of reserves these are: the western slope of the Andes in South America, the central African copper belt in Northern Rhodesia and Congo (Léopoldville), the Western United States, the Ural Mountains and the Kazakstan regions in the U.S.S.R., the Precambrian area of central Canada, and the Lake Superior region of North America.

Copper products in use that eventually will be discarded as scrap are another reserve being accumulated principally in industrial countries of the world. In the United States this resource, estimated to be more than 35 million tons, provides about one-fourth the annual supply.

Mining and metallurgical research has made immense quantities of low-grade ore available which otherwise would have been of no value as a source of copper. One of the most effective conservation practices is the reclamation of copper from scrap and another noteworthy practice is the recovery of copper by leaching low-grade material unsuited to concentration.

In the past 5 years strong demand and high prices, comparatively free from fluctuations, encouraged increased world mine production from new mines and accelerated rates at established mines. A new record for world production of 5.2 million tons was established in 1963. Although the United States remains as the largest producer of copper, its percentage of world production has declined from about 52 percent in 1926 to 23 percent in 1963. Chile, which had usually ranked in second place, was surpassed by Northern Rhodesia in 1953, 1954, 1960, and 1961. Estimated production of the U.S.S.R. placed it in second place in 1962 and 1963. Mine productivity capacity in the United States has increased about 12 percent since World War I. However, mine productivity in terms of output of copper per man-hour has increased more than sixfold.

The United States continued to be the largest copper consuming country in the world accounting for 30 percent of the world total. Since World War II, about half of the domestic consumption has been supplied by U.S. mine production, and one-fourth each by copper recovered from secondary materials and by imports. From 1959 through 1963, Chile supplied 44 percent of the imports of unmanufactured material; Canada 19 percent; Peru 15 percent; and the Republic of South Africa 6 percent.

Average annual prices in the United States have ranged from 5.67 cents per pound in 1932 to a peak of 41.88 cents per pound in 1956 (the high of 46 cents was reached in July 1956). The price of copper declined to 29 cents per pound in early 1961. Producers began curtailments of mine production and prices rose to 31 cents by May 1961 and producers' prices remained at that price through 1963, the longest period of price stability except when under Government control.

There is a rising trend in world consumption caused by expanding electrification, increased use of copper by the construction industry, and efforts to accelerate progress in developing nations. Appraising the future of the copper industry on the basis of past and current activities, there will be adequate sources of ore, ample processing equipment and copper should keep its share of the market for metals. The copper industry is confronted with technical and economic problems related to mining, processing, uses, and prices. Although there is ample reserve of ore for the domestic industry for some years, a fundamental problem is the assurance of a continuing supply at prices competitive to aluminum and other substitute materials.

BACKGROUND

Copper and gold were undoubtedly the first metals discovered and used by man. They are often found in the native state, are bright, pleasing in appearance, and easily worked. Industrially, however, copper was used first because when beaten it hardens sufficiently to permit primitive man to fashion utensils and sharp implements and weapons of lasting quality. Gold, which is soft, was used principally for ornamentation. The earliest history of copper is obscure, some theories have been advanced that its discovery was associated with Neolithic civilizations of the late stone age. Artifacts of hammered copper have been found among Chaldean remains that date back to 4500 B.C. and objects of copper that may be even more ancient have been excavated from Badarian graves in the Fayum of Egypt. Some writers believe that at least 20 centuries separated the first use of hammered copper and the beginning of copper smelting about 3800 B.C. This dates the discovery of copper circa 6000 B.C.

Little is known about prehistoric mining of copper although it seems certain that open-pit and underground mining methods were used. Diversity of opinion exists on the origin of smelting, but it is generally thought that the process first began about 3500 B.C. in Elam, an ancient country northeast of the valleys of

the Euphrates and Tigris Rivers. The most important deposits were in the eastern Mediterranean area, the Near East, central Asia, and Europe. It is thought that the copper used in southern Mesopotania (3500–3000 B.C.) came from deposits in Asia Minor that contain the same impurities that are present in the copper relics. These deposits also supplied the Assyrians much later and peaks of production from the area were between 2400–2000 B.C. and 1500–1200 B.C.

Definite records have been found that describe mining in the Sinai Peninsula about 3800 B.C. and the discovery of crucibles near the mines indicates that the early extraction of metal included some refining. Copper was produced in Egypt from Dynasty III (2600 B.C.) onward. It has been estimated that 10,000 tons of copper were produced in Egypt in 1,500 years. Egypt became dependent on imports of copper from Cyprus and Armenia in the 12th century. Copper mining in Cyprus began about 2500 B.C. and was successively under the dominion of Egyptians, Assyrians, Phoenicians, Greeks, Persians, and Romans. The same deposit is still being exploited and produced 29,000 tons in 1963.

Copper was used in China as early as 2500 B.C. and bronze castings were made about 2250 B.C. No mention of the source of copper is made in the epic of Shu King but it is traditional in China that metal came from the West. This is substantiated by the known existence of two trade routes to China, which traversed copper-producing areas, one by way of Altai and Lake Balkhash in Siberia and the other by Tarim and Turkestan.

In Europe, copper mines in Austria, Germany, France, Spain, Greece, and Tyrol were worked in the bronze age. Mines in Mitterberg in Tyrol probably were worked from about 1600 B.C. to the Hallstatt period in the iron age, about 800 B.C. Probably the most important copper deposits in Europe were those of Spain and Portugal, including the remarkable Rio Tinto ore body which is still being exploited. It is believed that the Phoenicians were acquainted with the mineral deposits of Britain as early as 1500 B.C. The Romans mined copper extensively in several parts of Britain, notably in Anglesey, Cumberland, and North Wales. It is probable that much of the metal was exported, one cake found near Llandudno was stamped "Scio Roma"—"to my partner in Rome."

Evidence of the first use of copper in North America was discovered by archeologists in pits on the Upper Peninsula of Michigan and on Isle Royale in Lake Superior. It has been estimated that there are thousands of pits on Isle Royale alone. The pits were excavated in mining and followed deposits of native copper from surface outcrops. A section of charred log found in one pit and subjected to carbon-dating methods was determined to be approximately 3,000 years old. Another piece from the same pit was tested and found to be about 3,800 years old. Working copper in the Americas seems to have stopped with the cessation of these operations about 1000 B.C. and was not resumed until A.D. 100–200 elsewhere on the continents. Copper was first produced in the American Colonies at Simsbury, Conn., in 1709 and a significant ore body was found in Orange County, Vt. (Ely mine), in 1820. It is not known whether or not any prehistoric race used copper from deposits in the Southwest, but it is reported that a Spanish officer in charge of a military post was shown croppings of native copper near Silver City, N. Mex., in 1800. Discovery of the ore deposits of Michigan in the early 1840's began a new era for copper production in the United States. Extensive ore bodies were found in Montana and Arizona during 1860–80 and smelter production from domestic ores increased from 728 tons in 1850 to 30,240 tons in 1880. In Bingham Canyon, Utah, the Utah Copper Co., later absorbed by the Kennecott Copper Corp., began exploitation of a large low-grade porphyry deposit in 1906. The success of this operation stimulated search for and development of other large deposits of similar characteristics, both in the United States and abroad. Development of the froth flotation process in the first two decades of the 20th century vastly increased the availability of copper contained in the large low-grade deposits which constitute most of the copper reserves.

The copper industry of Chile and Peru is an ancient one. It is known that aborigines worked some of the deposits before the arrival of the conquistadores. The Spaniards were more interested in gold than other metals and did nothing with the copper deposits until the beginning of the 17th century. The high-grade oxide and carbonate ores were worked in a primitive way for many years after. Chile ranked third as a world producer from 1801 to 1850 and was the largest producer in the world from 1851 to 1880. Production rapidly declined thereafter until the decade 1921–30 when Chile became the second largest producer, a position it has held almost consistently since.

When copper was mined first in central Africa is not known. Portugese explorers noted the production of copper and iron in Katanga in their 18th century reports. Ore bodies in the Katanga, Northern Rhodesia, and Trans-

vaal had been mined extensively and crosses of copper were items of commerce. Europeans arriving in the late 19th and early 20th centuries were shown outcrops of ore and ancient copper mines by Africans, resulting in the exploration and development of one of the most productive areas of the world.

SIZE AND ORGANIZATION OF THE INDUSTRY

The value of the copper content of ores produced in the United States in 1961 through 1963 exceeded that of the ore of any other metal except iron and averaged more than $734 million in the 3 years. Ore and waste handled at copper mines was more than the total material handled at mines of any other metal in 1960 through 1963 and averaged 394 million tons for the 4 years. The United States has been the largest copper-producing country in the world since 1883, except for 1934 when economic conditions adversely affected domestic production and Chile ranked first. The United States produced 23 percent of the world mine production in 1963. In that year, smelters in the United States produced 23 percent of the total world smelter production from domestic ore and an additional 1 percent from imported ore. Other principal copper-producing nations were the U.S.S.R., Chile, Northern Rhodesia, Canada, and the Republic of the Congo, in that order.

The primary copper industry in the United States is composed of approximately 200 companies engaged in the production and sale of copper. However, about a dozen companies produced more than 95 percent of the output. The major firms are vertically integrated and have mining, smelting, refining, fabricating facilities, and marketing organizations. Other large producers mine and process through the smelting or refining stage and many companies mine and concentrate their ore and ship the product to custom plants for smelting and refining.

In 1963, 25 mines accounted for 97 percent of the domestic output; the 5 largest produced 47 percent, and the 10 leading mines supplied 72 percent. Three companies, Kennecott Copper Corp., Phelps Dodge Corp., and The Anaconda Company usually account for about two-thirds of the annual domestic mine production. Kennecott and Phelps Dodge are the largest producers and supply about 31 percent and 21 percent, respectively, of each years total. The principal mining companies in the United States in 1963 were:

Company	Recoverable copper content of ore mined (short tons)	Percent of U.S. total
Kennecott Copper Corp	382,000	31
Phelps Dodge Corp	260,000	21
The Anaconda Company	121,000	10
Magma Copper Co	103,000	8
American Smelting and Refining Company	72,000	6
White Pine Copper Co	57,000	5
Inspiration Consolidated Copper Co	57,000	5
Tennessee Corp	33,000	3
Duval Corp	23,000	2
Total above companies	1,108,000	91
Total United States	1,213,000	100

Copper smelting capacity in the United States (exclusive of lake smelters in Michigan) totaled approximately 8.4 million tons of charge. The smelter of Phelps Dodge Refining Corp., at Laurel Hill, N.Y., was closed and dismantled in 1963 reducing the total charge by about 200,000 tons. Four companies control about 87 percent of the capacity. Copper smelting companies and their approximate percentage of the total U.S. smelting capacity are:

Company	Percent of total capacity (charge)
Phelps Dodge Corp. and Phelps Dodge Refining Corp	30
Kennecott Copper Corp	29
American Smelting and Refining Company	16
The Anaconda Company	12
Inspiration Consolidated Copper Co	4
San Manuel Copper Corp	4
American Metal Climax, Inc	2
Magma Copper Co	2
Tennessee Copper Co	1
Total	100

Lake smelter capacity in 1963 totaled 177,000 tons, as follows:

	Short tons
Calumet & Hecla, Inc	100,000
White Pine Copper Co	65,000
Quincy Mining Co	12,000

Tank capacities at electrolytic copper refineries in the United States in 1963 was about 1,964,000 tons. Three companies account for about 68 percent of total output. Refining companies and their approximate percentages of the U.S. electrolytic refinery capacity in 1963 are:

Company	Percent of total U.S. capacity
American Smelting and Refining Company	24
Phelps Dodge Refining Corp	23
Kennecott Copper Corp	21
International Smelting & Refining Co.[1]	12
American Metal Climax, Inc	8
The Anaconda Company	8
Inspiration Consolidated Copper Co.[2]	2
Lewis Mathes Co., Division of Cerro Corp	2
Total	100

[1] A subsidiary of The Anaconda Company.
[2] 28 percent controlled by The Anaconda Company.

Lake and fire refining capacities in the United States totaled 371,000 tons in 1963 or about 16 percent of the Nation's refinery capacity. Refining companies and their approximate percentage of the U.S. Lake and fire refining capacity are:

Company	Percent of total U.S. capacity
American Metal Climax, Inc	34
Kennecott Copper Corp	23
White Pine Copper Co	17
Calumet & Hecla, Inc	16
Phelps Dodge Refining Corp	7
Quincy Mining Co	3
Total	100

Fabricating establishments are the principal consumers of refined copper. They work the metal into semifinished forms such as sheet, strip, rod, tube, wire, and extruded and rolled shapes which are the raw materials for a vast industry which manufactures articles for final consumption or parts for products of other industries. About 35 companies are the important users of raw copper and are, for the most part, wire and brass mills. The larger fabricators, representing more than 50 percent of the total volume of business, are affiliated with the major copper producers, as follows:

Fabricating company	Associated with—
Chase Brass & Copper Co, Inc	Kennecott Copper Corp.
The Okonite Co	Do.
The Anaconda American Brass Co	The Anaconda Company.
Anaconda Wire & Cable Co	Do.
Phelps Dodge Copper Products Corp	Phelps Dodge Corp.
Calumet & Hecla, Inc.—Wolverine Tube Division	Calumet & Hecla, Inc.
C. G. Hussey & Co., Division of Copper Range Co	Copper Range Co.
New Haven Copper Co	Tennessee Corp.
Cerro Copper & Brass Co., Division of Cerro Corp	Cerro Corp.
Circle Wire & Cable Co	Do.

American Smelting and Refining Company has substantial stock interests in General Cable Corp. (31.7 percent) and Revere Copper & Brass Corp., Inc. (35 percent).

The more important fabricators not affiliated with the copper producers are:

Brass mills

Bohn Aluminum & Brass Corp.
Bridgeport Brass Co., Division of National Distillers & Chemical Corp.
The Bristol Brass Corp.
Chicago Extruded Metals Co.
Detroit Gasket & Manufacturing Co.
The Electric Materials Co.
Halstead Metal Products
International Silver Co.
Mueller Brass Co.
Olin Mathieson Chemical Corp.
Reading Tube Co., Division Progress Manufacturing Co.
Scovill Manufacturing Co.
Triangle Conduit & Cable Co., Inc.
U.S. Mint Services
Volco Brass & Copper Co.
Western Electric Co., Inc.

Wire mills

Copperweld Steel Co.
General Cable Corp.
Hatfield Wire & Cable Division, Continental Copper & Steel Industries, Inc.
Narragansett Wire Co.
Rods, Inc.
Rome Cable Corp.
Triangle Conduit & Cable Co., Inc.
Western Electric Co., Inc.

Following is a list of the principal secondary copper smelters in the United States in 1963:

Barth Smelting & Refining Co.
Benjamin Harris & Co.
W. J. Bullock, Inc.
Colonial Metals Co.
Elesco Smelting Corp.
Federal Metal Co.
Federated Metals Division (American Smelting and Refining Company)
George A. Avril Smelting Corp.
H. Kramer & Co. (include Ajax Metal Division)
I. Schumann & Co.
Interstate Smelting & Refining Co.
Liberman & Gittlen Metal Co., Inc.
Nassau Smelting & Refining Co.
North American Smelting Co.
R. Lavin & Sons, Inc.
River Smelting & Refining Co.
Roessing Bronze Co.
North Chicago Refiners & Smelters, Inc.
Northwestern Metal Co.

GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

Copper is widely distributed in nature. The earth's crust is estimated to contain an average of 70 parts per million. However, there are relatively few large copper-producing areas in the world despite its wide distribution. Many countries have some copper ore deposits; 8 countries each mined more than 100,000 tons of recoverable copper in 1963, 18 produced more

780-887 O—65——18

than 10,000 tons; and about 20 other nations recorded some output.

Most of the copper mined in the United States is produced in five Western States (91 percent in 1963) and approximately 85 percent of the remainder is obtained from Michigan and Tennessee. Most of the production in Chile comes from three large mines and the remainder comes from a number of small- and medium-size mines. Production from Peru is derived principally from two mines. Output in Congo (Léopoldville) comes from properties of one company and copper from Northern Rhodesia is produced from six large mines. Ontario and Quebec combined produced more than 70 percent of Canada's output but there has been a sharp upturn in production from British Columbia in the past few years. Estimates of production from the U.S.S.R. are usually included with data for Europe, although the production comes from the widely separated areas of Kazakstan, Uzbekistan, the Urals, Transcaucasia, West Siberia, and the Kola Peninsula. Yugoslavia recently became the second largest producer in Europe. Plans for development of extensive deposits in western Poland have been reported.

Concentrating and smelting facilities usually are situated near the principal mines and some process ore from smaller producers. There are eight primary smelters in Arizona, three in Michigan, and one each in Utah, Montana, Nevada, New Mexico, Tennessee, Texas, New Jersey, and Washington. The latter two smelters are at seaports. Of the smelters in Canada, three are in Ontario, two in Quebec and one in Manitoba. Mexico has two operating smelters and another is idle. Six smelters in Chile and two in Peru constitute the smelting industry in South America.

The Federal Republic of Germany has four smelters; Belgium and Sweden two; and Finland, Norway, Spain, and Yugoslavia each have one. Copper smelting is an important industry in Japan where eight companies operate several plants. A smelter operates in India and two in Turkey treat copper materials. The largest copper smelter in the world is in Northern Rhodesia where there are two others. One company has three smelters in the Republic of the Congo. Elsewhere, in Africa there are two operating smelters and one under construction in the Republic of South Africa, one each in Southern Rhodesia, South-West Africa, and Uganda. There are three smelters in Australia and one in Tasmania.

About 59 percent of the domestic electrolytic refining capacity and 61 percent of the output is accounted for in six refineries on the Atlantic coast in New York City, Carteret and Perth Amboy, N.J., and Baltimore, Md.; one each in Arizona, Missouri, Montana, Texas, Utah, and Washington supply the remainder. Three Michigan plants produce Lake copper and refineries in Maryland, New Jersey, New Mexico, and Texas produce fire-refined copper.

For many years before World War II, refining and smelting capacity in the United States exceeded the supply of domestic materials, and the excess capacity was used for the treatment of foreign crude material. Since the war, foreign producers have made great progress in building their own reduction works.

There are two electrolytic refineries of large capacity in Canada and one of small capacity in Mexico. Four establishments in Chile and one in Peru produce electrolytic copper. Numerous plants refine imported or domestic copper materials in Austria, Belgium, Finland, France, Federal Republic of Germany, Norway, Spain, Sweden, the United Kingdom, and Yugoslavia. In Africa, there are two refineries in the Republic of the Congo, four in Northern Rhodesia, and one each in the Republic of South Africa and Southern Rhodesia. Facilities of seven companies in Japan have an aggregate capacity of about 385,000 short tons. India and Korea each have a refinery, and Turkey has an electrolytic plant of small capacity and two fire refineries, only one of which is active. Two refineries in Australia and one in Tasmania have a total capacity in excess of a quarter million tons.

Although there are 20 fabricating plants in the New England States, most of the major establishments of the United States are in the Connecticut Valley area. Mid-Atlantic States have 26 plants; North-Central States 20; Southern States 1; and California 3.

The fabricating industry of Canada is situated in the provinces of Montreal, Quebec, and Ontario. Primary copper consumed in the manufacture of semifabricated products totaled 156,000 tons in 1962. The fabricating industry in Chile is small and production in 1961–63 averaged about 4,000 tons.

The fabricating industry of Europe, located in 16 nations excluding Soviet bloc nations, is large and uses approximately 2,150,000 tons of refined copper a year (the use of scrap and scrap alloys is excluded). It has been estimated that about 1,000,000 tons of refined copper is consumed in Soviet sphere countries.

Production of semimanufactures of selected European Nations in 1963 was as follows:

Country	Short tons
Austria	44,700
Belgium	136,900
France	392,300
West Germany	673,700
Italy	356,000
Denmark, Finland, Norway, Sweden	217,500
Switzerland	71,600
Spain	69,900
United Kingdom	795,200

Japan, the only other nation not in the Soviet sphere, having a large fabricating industry produces more than 620,000 tons of semifabricated products annually. India produces about 3,400 tons of the materials, slightly more than half of which are brass and bronze semimanufacturers.

Collection, preparation, and treatment of secondary materials is widespread. The collection of scrap is carried on in almost every community and in many, there are dealers that sort, bale, and otherwise prepare the scrap for sale and shipment to establishments that use it. These are primary and secondary smelters, ingot makers, brass mills, chemical plants, and other consumers. However, the principal source of unalloyed and alloyed copper scrap is in the heavily populated industrial areas and most of the plants that treat secondary materials are located near them. There are 60 secondary smelters in 21 States that treat scrap in addition to the brass and wire mills listed previously.

DEFINITION OF TERMS, GRADES, AND SPECIFICATIONS

Commercial copper is classified broadly by the method by which it is refined. Thus copper is described as electrolytic or fire refined. There are three basic classes of commercial copper that arise from the high affinity of molten copper for oxygen, and the methods employed for its control. They are designated as tough-pitch copper, oxygen-free copper, and deoxidized copper.

Electrolytic copper is that refined by electrolytic deposition. *Fire-refined copper* is refined by using a furnace process only. *Tough-pitch copper* is electrolytic or fire-refined copper cast in refinery shapes and containing a controlled quantity of oxygen in cuprous oxide. *Oxygen-free copper* is refined copper cast under a deoxidizing atmosphere that eliminates all cuprous oxide without using metallic or metalloidal deoxidizers. *Deoxidized copper* is refined copper freed from cuprous oxide through use of metallic or metalloidal deoxidizers. The terms "electrolytic" and "fire refined," when used alone, usually refer to either electrolytic or fire-refined tough-pitch copper without elements other than oxygen present in significant quantities. The five major classifications are applicable, through extension, to fabricator products made therefrom.

Resistivity is used instead of conductivity in designations of grades of copper. The value of 0.15328 ohm-gram/meter^2 is the International Annealed Copper Standard (IACS) for resistivity equal to 100 percent conductivity.

High conductivity copper has a minimum conductivity of 100 percent IACS in the annealed condition. *Casting copper* is fire-refined tough-pitch copper, usually derived from secondary metal and cast into ingot and ingot bars only for use in making foundry castings, but no wrought products. *Phosphorized copper* is a general term applied to copper deoxidized with phosphorus. It is the most commonly used deoxidized copper. *Arsenical copper*, *phosphorus-bearing copper*, *silver-bearing copper*, *tellurium-bearing copper* contain the designated element in amounts agreed upon between the supplier and the consumer. Any of these alloyed coppers can be produced as tough-pitch, oxygen-free, or deoxidized varieties.

Several types of each class of commercial copper are available in refinery shapes, and wrought and cast products. Eighteen such types are recognized by the American Society for Testing Materials in its Classification of Coppers. Refinery shapes and fabricators' products, currently produced in commercial forms, are listed in table 1.

Several refinery shapes are made depending partly on the end use of the copper.

Wire bar is a refinery shape for rolling into rod (and subsequent drawing into wire), strip, or shape. Wire bars are approximately 3½ to 5 inches square in cross section, usually from 38 to 54 inches in length, and weighing from 135 to 420 pounds. They are tapered at both ends when used for rolling into rod for subsequent wire drawing and may be unpointed when used for rolling into strip. Cake is used for rolling into plate, sheet, strip, or shape. It is rectangular in cross section of various sizes and ranges from 140 to 4,000 pounds or more in weight. Billet is the refinery shape used primarily for tube manufacture. It is circular in cross section, usually 3 to 10 inches in diameter and in lengths up to 52 inches; weight from 100 to 1,500 pounds. Ingots and ingot bars are employed for alloy production (not fabrication). Ingots usually weigh from 20 to 35 pounds and ingot bars from 50 to 70 pounds. Both usually are notched to facilitate breaking into smaller pieces and are used for remelting. Unmelted flat plate produced by electrolytic refining is called cathode. The customary size is about 3 feet square and about ½ to ⅞ inches thick, weighing up to 280 pounds.

TABLE 1.—*Classification of coppers*

Designation	Type of copper	Forms in which available							
		From refiners				From fabricators			
		Wire bars	Billets	Cakes	Ingots and ingot bars	Flat products	Pipe and tube	Rod and wire	Shapes
Cath	Electrolytic cathode	Available in cathodes only.							
		Tough pitch coppers							
ETP	Electrolytic tough pitch	X	X	X	X	X	X	X	X
FRHC	Fire-refined high conductivity tough pitch	X	X	X	X	X	X	X	X
FRTP	Fire-refined tough pitch		X	X	X	X	X		X
ATP	Arsenical tough pitch		X	X		X	X	X	
STP	Silver bearing tough pitch	X	X	X	X	X	X	X	X
SATP	Silver bearing arsenical tough pitch		X	X		X	X		
CAST	Casting				X				
		Oxygen-free coppers							
OF	Oxygen-free without residual deoxidants	X	X	X		X	X	X	X
OFP	Oxygen-free, phosphorus bearing	X	X	X		X	X	X	
OFPTE	Oxygen-free, phosphorus and tellurium bearing.		X					X	X
OFS	Oxygen-free, silver bearing	X	X	X		X		X	X
OFTE	Oxygen-free, tellurium bearing		X					X	X
		Deoxidized coppers							
DHP	Phosphorized, high residual phosphorus	X	X	X		X	X	X	X
DLP	Phosphorized, low residual phosphorus		X	X		X	X	X	X
DPS	Phosphorized, silver bearing		X	X		X	X		X
DPA	Phosphorized, arsenical		X			X	X		
DPTE	Phosphorized, tellurium bearing		X					X	X

Definitions of fabricators' copper products follow:

Wire, a solid section including rectangular flat wire but excluding other flat products, furnished in coils or on spools, reels, or bucks. Flat wire may also be furnished in straight lengths.

Tube, a hollow product of round or any other cross section, having a continuous periphery.

Pipe, seamless tube conforming to the particular dimensions, commercially known as Standard Pipe Sizes.

Shape, a solid section, other than rectangular, square or standard rod, and wire sections, furnished in straight lengths. Shapes are usually made by extrusion, but may also be fabricated by drawing.

Flat product, a rectangular or square solid section of relatively great length in proportion to thickness. Included in the designation flat product depending on the width and thickness, are plate, sheet, strip, and bar. Also included is the product known as flat wire.

Rod, a round, hexagonal, or octagonal solid section. Round rod for further processing into wire (known as hot rolled rod, wire-rod, or redraw wire) is furnished coiled. Rod for other uses is furnished in straight lengths.

Copper powder, finely divided copper particles produced by (1) high velocity atomization of molten copper with streams of compressed gas, steam, or water; (2) gaseous reduction of finely divided oxides; and (3) precipitation from solutions.

The various types of copper are graded by the American Society for Testing Materials (ASTM) principally according to their chemical composition and electrical resistivity. Specifications adopted for these coppers are as follows:

B4–42 Lake copper wire bars, cakes, slabs, billets, ingots, and ingot bars (must originate on the Northern Peninsula of Michigan).

(a) Low-resistance Lake copper—minimum purity of 99.900 percent, silver being counted as copper.

	Resistivity, maximum, international ohm-gram/meter[2]
Wire bars	0.15328
Cakes, slabs, and billets:	
For electrical use	.15328
For other uses	.15694
Ingots and ingot bars	.15694

(b) High resistance Lake copper—minimum purity of 99.900 percent, silver and arsenic being counted as copper; resistivity greater than 0.15694 international ohm-gram/meter[2] at 20°C.

B5–43 Electrolytic copper wire bars, cakes, slabs, billets, ingots, and ingot bars—minimum purity 99.900 percent, silver being counted as copper.

	Resistivity, maximum, international ohm-gram/meter[2]
Wire bars	0.15328
Cakes, slabs, and billets:	
For electrical use	.15328
For other uses	.15694
Ingots and ingot bars	.15694

B115–43 Electrolytic cathode copper—minimum purity of 99.90 percent, silver being counted as copper. The copper shall have a resistivity not to exceed 0.15328 ohm-gram/meter[2] at 20°C (annealed).

B170–59 Oxygen-free electrolytic copper wire, bars, billets, and cakes—minimum purity of 99.95 percent, silver being counted as copper. Resistivity not to exceed 0.15328 ohm-gram/meter[2] at 20°C (annealed). Test samples shall be free from cuprous oxide as determined by microscopic examination at 75 X magnification. Prepared wire samples, annealed at 800° to 875°C for 20 minutes in hydrogen, shall withstand four 90° bends (2 each in opposite directions) without fracture.

B72–60 Fire-refined casting copper—must conform to the following requirements as to chemical composition:

	Grade A percent	*Grade B percent*
Copper plus silver, minimum	99.75	99.50
Arsenic, maximum	.0075	.10
Antimony, maximum	.012	.012
Bismuth, maximum	.003	.003
Iron, maximum	.010	.010
Lead, maximum	.100	.30
Nickel, maximum	.10	.10
Oxygen, maximum	.10	.10
Selenium, maximum	.040	.040
Sulfur, maximum	.01	.01
Tellurium, maximum	.014	.014
Tin, maximum	.025	.05

B216–49 Fire-refined copper for wrought products and alloys—must conform to the following requirements as to chemical composition. (No resistivity specifications.)

	Percent
Copper plus silver, minimum	99.88
Arsenic, maximum	.012
Antimony, maximum	.003
Selenium plus tellurium, maximum	.025
Nickel, maximum	.05
Bismuth, maximum	.003
Lead, maximum	.004

Copper-Base Alloy Terms

Copper and copper-base alloys comprise a series of metals that include all the alloys which are at least 40 percent copper and where the amount of copper is not less than the amount of any other constituent. There are essentially four well-known copper-base alloys—brass, bronze, nickel-silver, and cupro-nickel. Modern nomenclature for certain compositions departs from the original concept that brasses are copper-zinc alloys and bronzes principally copper and tin. Metallurgical research has developed important new alloys and necessitated revision of many original, simple definitions.

Brass may be defined as any copper-base alloy containing zinc as the principal alloying constituent, with or without smaller quantities of other elements. Some of the alloys known as nickel-silver could be termed "brasses," but these alloys also possess enough distinctive qualities to warrant separate classification. There are alloys that are definitely brasses by definition, yet have names that include the word "bronze;" for example, *commercial bronze* containing 90 percent copper and 10 percent zinc.

The term *bronze* is seldom used alone and the copper-tin alloys have come to be known as *phosphor bronze* because of the small residual phosphorus content. With a suitable modifier the term *bronze* also extends to various copper-base alloy systems where the principal alloying element is other than tin or zinc. These systems include *aluminum bronzes*, *beryllium bronzes*, and *silicon bronzes*.

Nickel-silver, formerly known as German silver, is a copper-alloy containing both nickel and zinc. Its name derives from its predominantly silvery color. *Cupro-nickels* are essentially copper and nickel, the nickel content usually 10, 20, or 30 percent. In addition to these, there are many special and proprietary alloys that include *aluminum-tin bronze*, *aluminum-silicon bronze*, *cadmium bronze*, *chromium copper*, *beryllium copper*, *leaded copper*, and *selenium copper*.

Copper-base alloys are also grouped in two classes according to specifications required in the processes of fabrication. These two classes are wrought alloys and casting or foundry alloys. The *wrought alloys* of copper are regarded as only those made by alloying the various components and casting into slabs, cakes, or billets for hot or cold rolling, drawing, extrusion, or forging. *Casting alloys* are made from a complex assortment of industrial nonferrous scrap by scientific selection, smelting, and refining processes. Many compositions suitable for casting in sand or permanent molds are entirely unfit for working operations.

Designations of copper and copper-base scrap as given by the American Metal Market (*3*)[2] are—

No. 1 Copper Wire: Consists of clean, untinned, uncoated, unalloyed copper wire and cable, heavy field wire, heavy armature wire, not smaller than No. 16 B. & S. wire gage to be free from burnt copper wire which is brittle and foreign attachments.

No. 2 Copper Wire: Consists of miscellaneous clean copper wire which may contain a percentage of tin-coated, lead-coated, solder-coated wire, enameled wire, and copper wire with soldered ends. To be free of hair wire or burnt wire which is brittle. The tin-coated, lead-coated, solder-coated and enamel wire not to be over 15 percent of the total weight.

[2] Italicized numbers in parentheses refer to items in the list of references at the end of this chapter.

MIXED HEAVY COPPER: Consists of copper clippings, clean copper pipe and tubing, copper plates and pieces, copper wire and segments, which may contain tin-coated, solder-coated, lead-coated copper scrap and copper scrap with soldered ends, but to be free of hair wire or burnt which is brittle.

LIGHT COPPER: Consists of the bottoms of copper kettles and boilers, bath tub linings, hair wire, burnt copper wire which is brittle, roofing copper and similar copper, free from radiators and fire extinguishers, brass and bronze screening, excessive lead and solder, readily removable iron, old electrotype shells, unclean gaskets and free of excessive paint, tar and scale.

COMPOSITION OR RED BRASS: Consists of red brass scrap, valves, machinery bearings and other parts of machinery, including miscellaneous castings made of copper, tin, zinc and/or lead, no piece to measure more than 12 inches over any one part or to weigh over 100 pounds, to be free of railroad boxes, and other similarly excessively leaded material, cocks and faucets, gates, hot pieces, ingots and burned brass, aluminum bronze, manganese-bronze and iron.

COMPOSITION TURNINGS: Consists of turnings from red brass composition material and should be sold subject to sample or analysis.

COCKS AND FAUCETS: Consists of mixed clean red and yellow brass, including chrome or nickel plated, free of gas cocks and beer faucets, and to contain a minimum of 35 percent red.

NEW BRASS CLIPPINGS: Consists of the cuttings of new unleaded yellow brass sheet, to be clean and free from foreign substances and not to contain more than 10 percent of clean brass punchings under ¼". To be free of Muntz metal and naval brass.

NO. 1 ROD TURNINGS: Consists of strickly rod turnings, free of aluminum, manganese, composition, Tobin and Muntz metal turnings; not to contain over 3 percent free iron, oil or other moisture; to be free of grindings and babbitts; to contain not more than 0.30 percent tin and not more than 0.15 percent alloyed iron.

BRASS ROD ENDS: Consists of new, clean rod ends from free turning brass rods and forging rods, not to contain more than 0.30 percent tin and not more than 0.15 percent alloyed iron. To be free of Muntz metal and naval brass or any other alloys. To be in pieces not larger than 12" and free of foreign matter.

AUTO RADIATORS: Consists of mixed automobile radiators, to be free of aluminum radiators, and iron finned radiators. All radiators to be subject to deduction of actual iron.

REFINERY BRASS scrap contains minimum of 60 percent copper, not more than 5 percent iron, with the balance made up predominantly of zinc; free of grindings.

TECHNOLOGY

Geology

Copper ore is found in many types of deposits that occur in a variety of host rocks. The period of their formation varies from Precambrian to Tertiary. Most of them are associated in time and place with igneous activity but the origin of some that occur in sedimentary rocks, seemingly far distant from such activity is the subject of some debate. Extrusive and intrusive rocks associated with many of the deposits are of intermediate composition and the intrusives—monzonite and diorite— have quartzoze and porphyritic phases.

Porphyry copper deposits account for a large percentage of the U.S. production and much of the world output. They contain most of the estimated commercial copper reserve of the world. Porphyry is used commonly to designate any igneous rock having larger crystals imbedded in a finer grained groundmass. It is more loosely and incorrectly applied in the mining industry to any igneous rock especially when occurring with ore. In a commercial sense the term "porphyry copper deposits" is not restricted to ore in porphyry but refers to deposits characterized by large size and uniform dissemination of copper bearing minerals through parts of the intrusive mass itself or through the adjacent rocks into which the porphyry has intruded. The ore minerals occur as isolated specks or in small veinlets. Porphyry deposits usually are low in average copper content and may contain gold, silver, molybdenum, and some minor metals in quantities sufficient to warrant their recovery. Many of the deposits were formed by secondary enrichment of lean primary ore by weathering or some other surficial processes, resulting from the downward percolation of copper-bearing solutions from which the copper was deposited at lower levels. Three zones resulted from this action, an upper or leached zone containing oxide minerals and underlain by a zone of enrichment which in turn is underlain by a zone of primary mineralization. Oxide and carbonate minerals occur in the leached zone; chalcocite as the principal mineral and lesser amounts of covellite are found in the zone of secondary enrichment; chalcopyrite and pyrite are the principal minerals in the zone of primary mineralization, which in some deposits contains sufficient copper to be ore. Some of the deposits do not have a great vertical range but the mine at Bingham Canyon, Utah, has attained a depth of more than 2,000 feet below the highest point of stripping. The major porphyry deposits of the world are in the Southwestern and Western United States, Chile, Peru, and U.S.S.R.; there are smaller deposits in Canada, Mexico and southeastern Europe. The first porphyry-type deposits to be developed in Africa is being prepared for production in the Republic of South Africa.

Associated with the porphyry deposits in time and frequently in place are vein, pipes, and bedded deposits in sedimentary rocks. Vein deposits were formed by ore minerals filling open fissures or replacing adjacent wall rock which had been brecciated by faulting or fracturing. The simplest veins are those which occupy a single fissure. Large deposits of this type are uncommon but the Magma and Old Dominion veins at Superior and Globe, Ariz.,

approach it. Vein systems are complex and intricate in other districts, such as Butte, Mont., and Morenci, Ariz. At least three ore-bearing and several non-ore-bearing fissure systems have been recognized in Butte. Some of the veins are large enough to be mined as a single unit; in some parts of the areas, however, several small veins are mined as a mass.

Bedded deposits in sedimentary rock include what are known as contact or pyrometasematic deposits and those formed by replacement of sedimentary rocks, frequently limestone, outward from fissures. The two types are not sharply separated. The typical contact deposit are replacements in limestone or dolomite by silicates, iron oxides, and sulfides of iron and copper. They occur at or near the contact of a sedimentary rock and an intrusive body. Replacement deposits are those in which certain beds of limestone are replaced outward from fissure with or without the formation of silicates. Part of the large deposits of Bisbee, Ariz. and the replacement deposits at Bingham Canyon, Utah, are examples of these occurrences and other deposits of less importance have been mined.

The copper ores of the central African copper belt, that contribute about 18 percent of the supply of copper, occur in sedimentary deposits underlain by metamorphic and igneous rock and overlain by younger sediments. The sedimentary beds have been faulted and folded into a series of complex anticlines and synclines. The anticlines have been eroded and the synclines form basins where concentrations of copper minerals are found. The deposits contain oxidized ore near the surface which grades through mixed oxide and sulfide ores to large deposits of sulfides at depth. The sedimentary deposits of Dzhezkagan in the U.S.S.R. are reported to be similar to those of Northern Rhodesia except they contain a little lead. The deposits occur in continental sandstones, shales, and conglomerates in which there are several ore-bearing horizons.

The deposits of the Precambrian Canadian shield are of the next importance economically. The nickel-copper deposits of Sudbury are perhaps the most unusual. The dominant geologic feature of the district is a spoon-shaped sheet of intrusive norite, which is underlain by an ancient complex of granite, gneiss, schist, metamorphosed sediments, and various eruptives. The nickel-copper ore occurs predominantly near the base of the norite but partly in underlying rocks as pyrrhotite, pentlandite, and chalcopyrite associated with pyrite and magnetite. Gold and silver occur in the native state and tellurides and platinum-group metals occur as arsenides and other rare combinations.

The native copper deposits of the Lake Superior area occur in shoots in the tops of certain lava flows, in conglomerates interbedded with the flows and in sandstone. Deposits of this type have substantial vertical depth with no notable change in mineralization. The ores are usually low-grade concentrating ores, although masses of copper are encountered. Other economic deposits in the area occur as disseminated chalcocite in beds of shale.

Lenticular deposits in schistose rock include those in which the primary mineralization consists mainly of sulfides of iron, copper, and zinc, commonly as replacement of the host rock. Such deposits usually are found where erosion has been deep and do not seem to be associated with igneous stocks. They occur in the Appalachian region, the western part of the United States, and British Columbia. Supergene alternation of such deposits usually produces a thin zone of enriched sulfides, as at Ducktown, Tenn. and Iron Mountain, Calif., but sometimes the enrichment is deep as at Jerome, Ariz.

Mineralogy

Copper is found in nature in numerous minerals and in various combinations with other elements. Of about 165 known copper minerals, only about 12 are commercially important; and 6 minerals are the source of over 95 percent of the copper mined. The principal copper minerals are as follows:

Mineral	Composition	Specific gravity	Copper, percent
Native: Native copper	Cu	8.8–8.9	100
Oxides:			
Cuprite	Cu_2O	6.0	88.8
Tenorite	CuO	5.8–6.3	79.8
Malachite	$CuCO_3Cu(OH)_2$	3.9–4.03	57.3
Azurite	$2CuCO_3Cu(OH)_2$	3.77	55.1
Chrysocolla	$CuSiO_32H_2O$	2.0–2.4	36.0
Antlerite	$Cu_3SO_4(OH)_4$	3.39	54.0
Brochantite	$Cu_4SO_4(OH)_6$	3.9	56.2
Atacamite	$CuCl_2·3Cu(OH)_2$	3.75–3.77	59.4
Sulfides:			
Chalcopyrite	$CuFeS_2$	4.2–4.3	34.5
Bornite	Cu_5FeS_4	4.9–5.4	63.3
Chalcocite	Cu_2S	5.5–5.8	79.8
Covellite	CuS	4.9–5.0	66.4
Enargite	Cu_3AsS_4	4.43–4.45	48.3
Tetrahedrite	$Cu_8Sb_2S_7$	4.7–5.0	52.1
Tennantite	$Cu_8As_2S_7$	4.7–5.0	57.0

Copper-bearing minerals are classified in three important groups. Primary or hypogene minerals are those deposited at depth in the earth by processes that may be related to igneous activity. Examples of these are bornite, chalcopyrite, and enargite. Some complex minerals are also primary, but minerals of this type are not abundant in economic deposits. The second group is composed of oxide copper supergene minerals commonly formed by weathering of copper sulfides exposed to erosion. Cuprite,

malachite, azurite, and chrysocolla are the chief minerals of the supergene zones of copper deposits where a reactive gangue is present. Brochantite and atacamite are found in the upper portions of ore bodies in arid regions. The third group, the simple sulfides, chalcocite, and covellite, are predominant in the zone of secondary enrichment. These minerals are formed when copper is leached from sulfides near the earth's surface, carried downward in solution, and precipitated at water level.

The copper minerals found most frequently at the surface are the green and blue copper carbonate and the green silicates. These colors are distinctive and rock with a very small percentage of copper may be vividly green. Cuprite, tenorite, native copper, atacamite, chalcanthite, and occasionally other rare copper minerals are found in outcrops; these minerals, together with the carbonates and silicate minerals, are formed by the weathering of copper sulfides. Chalcopyrite and, to a smaller extent, bornite may exist in outcrops or in float, but when found at the surface in arid districts usually they are in the form of kernels surrounded by alteration products. Copper sulfides usually are associated with pyrite and other iron sulfide minerals.

Copper ores vary in type (whether sulfide or oxide), in the valuable metals occurring in them, in their tenor, and in the kind of associated gangue present. They are commonly distinguished as oxidized ores or sulfide ores. These may range between high grade and low grade, which roughly expresses their copper content.

A large percentage of copper produced comes from sulfide ore deposits which are natural mixtures containing copper-bearing sulfide minerals and associated gangue minerals that are either of valueless mineral content or of subordinate economic importance. These ores comprise three groups. In the first, ore minerals of the porphyry and central African types are chalcocite, chalcopyrite, and bornite associated with pyrite. The second group consists of the cupriferous pyrite bodies which contain abundant pyrite and pyrrhotite. Notable examples are at Jerome, Ariz., Rio Tinto, Spain, and the island of Cyprus. The ores of the third group carry some of the copper in enargite or tenantite which contains arsenic. Well-known deposits of this type are at Butte, Mont., Bor, Yugoslavia, and Tsumeb, South-West Africa. The gangue may consist simply of the minerals making up the host rock, or it may be composed of various other minerals developed during the the general ore-forming process, or it may occur as a combination of these two groups. Thus the gangue might consist of a sulfide, such as pyrite, along with quartz, sericite, calcite, barite, etc. From an ore like this, in addition to the principal value in copper, pyrite might be reclaimed as a byproduct for its sulfur, and barite might be recovered to be used in well-drilling muds.

An oxidized copper ore is also a natural mixture of oxidized copper minerals and gangue. Examples would be the deposits of malachite and azurite ores in dolomite of the Congo (Léopoldville) and the unusual oxide mineral assemblage at Chuquicamata, Chile, consisting of atacamite, brochantite, and other sulfates.

Native copper frequently occurs in small quantities in the zone of oxidation, but in a few deposits it is the ore mineral. In these deposits the gangue may be conglomerate or basalt, as in the ores from the Lake Superior district in Michigan, or sandstone, as in the much smaller deposits at Corocoro, Bolivia.

Prospecting and Exploration

Prospecting is the search for ore occurrence, and exploration is the work involved in gaining knowledge of the size, shape, position, and value of an ore body. These two activities, although quite different in purpose, use the same tools. From a practical standpoint, separation of prospecting from exploration is difficult and consequently prospecting and exploration of copper deposits are treated herein as a unit. Most copper mines have been discovered by surface prospecting often using distinctive coloration of rocks as a guide. However, the exploration responsible for the development and expansion of many of the mines resulted from costly geologic and geophysical investigations, exploratory drilling, and excavation of underground workings.

Tracing float, trenching, and test pitting were the usual methods formerly used. Large exploration companies now use geochemistry, airborne geophysical methods, and photogeology to select areas for preliminary exploration. Favorable appearing areas are studied more intensively by checking geophysical anomalies using corresponding ground techniques, detailed geochemical work and geological mapping, and possibly shallow drilling, pitting, stripping, and trenching. If results are encouraging, more intensive exploration is conducted, usually to obtain representative samples. The exploratory program is expanded to delineate the ore body, determine its grade and mineralogic nature, plan mining methods and equipment installation, project the scale of operation, and investigate other technical and economic factors essential to the establishment of a mining enterprise.

Geophysical prospecting is used to measure and interpret anomalous physical or physio-

chemical phenomena within the earth's crust. It utilizes electric, gravimetric, magnetic, seismic, and thermic properties of rocks and minerals, either those natural to them or produced artificially. Geophysical methods disclosed information that encouraged the development of three outstanding ore bodies; Pima mine in Arizona where an ore body lays beneath 200 feet of valley fill; the buried Lynn Lake nickel-copper deposit; and the copper-zinc-silver deposits discovered in 1963 north of Timmins, Ontario.

Exploration to define the size and configuration of a newly found ore body and to determine its mineral content is usually accomplished by boring. The principal types of drills used for this purpose are churn drills, rotary drills, diamond drills, and percussion drills. Diamond drilling is most widely used because of its speed, adaptability for directional drilling, and recovery of core for analysis and other studies. Approximately one-half of the exploratory and development work done in 1963 on domestic copper deposits was accomplished by core drilling and about one-third by rotary drilling.

Mining

Open-pit (or open-cut) and underground methods are used in mining various types of copper deposits. Open-pit mining accounted for 74 percent of the copper and 81 percent of the ore mined in the United States in 1963. The choice of method is determined by the size, configuration, and depth of the ore body, which largely determine the relative costs of mining by the two methods. Topography, climate, existing surface improvements, availability of skilled labor, and availability of capital also affect the choice of method. Large porphyry-type deposits are amenable to surface mining if they are near enough to the surface so that the cost of removing overburden is not prohibitive. If the ratio of waste-to-ore is too large, these deposits are mined by caving methods by which low costs are achieved through mass production. Veins and deposits of lenticular or tabular shape usually are mined by underground workings that permit extraction of a large percentage of ore and provide support of the workings to prevent loss of ore in adjacent ore bodies or the destruction of surface installations.

Although open-pit mining appears simple, good management and careful planning are essential to achieve low mining costs. The shape and position of the ore body must be predetermined to allow planning for access, stripping disposal, bench design, pit slopes, transportation, equipment, and other requirements of handling large quantities of ore and waste. The advantages of open-pit mining are the ease with which the rate of mining can be changed, low shutdown expense, the ability to mine selectively, practically complete extraction of ore within pit limits, a high rate of productivity by labor, and elimination of many hazards inherent to underground mining. Disadvantages of the method are heavy capital outlay for equipment and, where the amount of overburden is large, a corresponding capital expenditure for stripping. Time lapse between the beginning of stripping and actual production may be quite long and can be a disadvantage if market conditions change adversely during the development period.

Benches in open-pit copper mines range from 25 to 60 feet. The height is selected to give maximum digging efficiencies, but may be controlled by ore-waste separation. Hardness of rock and stability of faces also affect the height.

The cycle in open-pit ore extraction consists of drilling, blasting, loading, and transportation. Primary drilling is sinking vertical or near vertical blast holes behind the face of an unbroken bank. Secondary drilling is required to break boulders too large for shovels to handle or to blast unbroken points of rock that project above the digging grade in the shovel pit. Recent advances in drilling and blasting include the use of rotary drills instead of churn drills and use of lower cost ammonium nitrate, sensitized by diesel fuel or some other suitable petroleum product as an efficient blasting agent.

Ore and waste are loaded by full-revolving power shovels. At many mines, shovels with 4- to 6-cubic-yard capacities are used but large mines have shown a tendency to use 7- to 10-yard shovels, and two 12-cubic-yard shovels were installed recently at the Utah Copper mine.

Haulage is by truck of large capacity for short hauls and by train for longer ones. However, the trend is toward more of the haulage by larger trucks. Overburden and ore are moved at some mines by tractor-drawn scrapers which have been useful in preparing approaches or drop cuts. Skip-ways and belt conveyors have been installed at other mines for ore handling.

A substantial portion of the world production is mined from deep deposits by underground methods which are designed for the extraction of ore with the greatest safety at minimum costs. Most of the modern underground mining of copper is done by two methods, caving and supported stopes.

Caving methods are of three distinct types, block caving, top slicing, and sublevel caving. Block caving is a low-cost mining method amenable to mass production from large, homogene-

ous, and rather weak ore bodies. The use of the method requires detailed engineering study of an ore body by systematic and extensive exploration and sampling. Adequate development, preparatory work, transportation systems, and ore drawing control are equally important. This method consists of dividing suitable ore bodies into blocks of predetermined size and undercutting each to permit rock stresses to cave and crush the ore to sizes that can be handled easily. The method is nonselective and lean sections of ore and waste will be broken and drawn with the ore. The method also results in some loss of ore. Top slicing is an important modification of caving where ore is extracted by excavating a series of horizontal or inclined timbered slices, beginning at the top of the ore body and progressing downward. After each slice is mined out the overlying rock is caved by blasting the timber supports or allowing them to crush. The floor of each slice is covered with a mat of timbers to separate the caved material from the solid ore beneath. Top slicing is more costly than block-caving but allows recovery of almost all the ore and is applicable to smaller and more irregular ore bodies. Sublevel caving is somewhat similar to top slicing in that ore is mined progressively downward in horizontal slices. The fundamental difference is that the slices are thicker in sublevel caving. The method is rarely used in copper mining.

Supported stopes are of two types, naturally supported and artificially supported. The simplest form of naturally supported stopes are open stopes in which the entire ore body is removed from wall to wall without any support other than occasional props, stulls, or cribs to hold local patches of insecure ground. The method is applicable to relatively small ore bodies with strong walls and roofs. Open stopes with pillar support are used when extracting ore from wider ore bodies or those that occur as bedded deposits. Pillars of definite size and spacing are left in room and pillar methods of mining. Sometimes low-grade portions of the ore are left as pillars.

Artificially supported stopes are those in which installation of systematic temporary or permanent support of ground is part of the mining cycle. Three principal types are used in copper mining.

Shrinkage stoping is applied to relatively thin, tabular deposits dipping at angles greater than 50°, having few waste inclusions and firm walls that stand well without sloughing. Ore is mined in successive horizontal or inclined slices, working upward from the bottom of a block of ore. Only enough of the broken ore is drawn from the stope after each cut or slice to allow working space between the broken and unbroken ore. The broken ore serves as a floor upon which to work when drilling for the next successive cut and also provides supports for the stope walls. After mining has been completed to the upper limits of the block, all ore is drawn leaving the stope empty.

Cut and fill stoping is applicable for extracting firm ore from deposits enclosed in walls, one or both of which may be weak. It is used also to mine deposits too irregular to be mined by shrinkage stoping. Ore is excavated by successive flat or inclined cuts working upward as in shrinkage stoping, but the ore is removed after mining each slice. The slice is then partly filled with waste rock, milltailing, sand, or other material to support the walls, leaving a working place for mining the next slice.

Timbered stoping is used to mine regular or irregular ore bodies in which the ore and/or the walls are too weak to stand for a brief time over a short span and where caving of adjacent rock must be prevented. The most elaborate method of timbered stoping is the square-set method by which the back and walls are supported by framed timber forming a network of contiguous, hollow rectangular prisms, in the place previously occupied by ore. The ore is removed in small, rectangular blocks, usually just large enough to provide space for a set of timber. Usually stopes are mined in floors one above the other and the timbers of one floor are framed into those of the lower one. Timbered stoping is usually accompanied by filling and, in heavy ground, the sets are filled with waste promptly after they are installed.

Beneficiation

Some copper ores of sufficient copper content are smelted directly. However, nearly all the copper now produced, or that will be produced in the near future is from sulfide, oxide, or native copper ores that are first subjected to a physical separation of minerals by upgrading processes known as milling or concentration. The principal steps in concentration are crushing, grinding, and separation of valuable minerals from waste material. The products of upgrading are: a concentrate, which contains most of the ore minerals and some gangue; and tailing which contains the waste material and a portion of valuable minerals. The method of separating copper minerals from gangue is determined by the chemical form, size, density, and surface characteristics.

At concentrators of large capacity, sulfide minerals are recovered by flotation, a highly developed and universally used process. Some small operations, however, employ gravity

methods such as jigs or vibrating tables. Flotation involves the separation of different mineral particles from each other in a liquid pulp. Finely ground ore is agitated in water with air or other gases. Various oils and chemicals are added to cause the selected minerals to adhere and rise to the surface where they are removed in the froth. Other minerals remain suspended in the pulp. Originally, recovery of valuable minerals in only one product was accomplished. With the advancement of the art, the principle of selective flotation was evolved and two or more relatively clean products can be recovered from complex material. Typical selective or differential flotation practices in copper milling are separation of copper sulfides from pyrite, recovery of molybdenum from copper concentrate, and recovery of a copper concentrate from complex lead-zinc-copper ore. More than 90 percent of the copper contained in the ore is recovered at large concentrators using good milling practices. To a certain extent, the copper content of the concentrate is related to the mineralogical composition of the ore treated, thus ore with chalcocite as the principal mineral should yield a higher grade concentrate than one containing chalcopyrite and pyrite. The copper content of concentrates produced in the United States ranges from 20 to 35 percent.

The treatment of mixed ore, containing both sulfide and oxide minerals, depends on the relative proportions of the two types of minerals. If sulfides predominate, flotation is used, employing reagents that favor flotation of oxide minerals. When the ore contains almost equal amounts of sulfide and oxide minerals, combinations of leaching and flotation are used. By one method, the ore is leached with sulfuric acid and the residue is treated in a concentrator where sulfide minerals are recovered by flotation. In another process, leach-precipitation-float (LPF), the oxide minerals are converted to metallic copper which readily responds to flotation with sulfide minerals. Sponge iron is usually used to precipitate copper prior to flotation.

Recovery of copper carbonate minerals either alone or with copper sulfides by sulfidation and flotation has been achieved with a certain degree of success. Leaching, however, is the method usually used in the United States to recover copper from oxide minerals.

Leaching oxide or mixed oxide-sulfide ores is unfeasible if the gangue is acid consuming and the economic flotation of silicate minerals remains unsolved. Research by the Bureau of Mines on the segregation process and by an African company on TORCO (treatment of refractory copper ores) shows promising results. The two processes are similar in that they involve heating ore with a halide salt and carbonaceous material. Basically the process proceeds in four stages: decomposition of salt and formation of hydrochloric acid; the acid and copper minerals form volatile cuprous chloride; the cuprous chloride is reduced to metallic copper on the carbon particles; and the metallic copper is recovered by flotation.

Recent improvements in milling practices include automation, autogenous grinding, and classification by cyclones.

Leaching

Copper produced in the United States from oxide ores is recovered principally by hydrometallurgical methods. Excluding copper produced from oxide minerals by the LPF process, production by leaching is approximately 9 percent of the U.S. output. The usual practice is to leach oxide ores with dilute sulfuric acid, but leaching mixed oxide-sulfide ore is more difficult. Ferric sulfate is an active solvent of most oxidized copper minerals and to an extent is effective on free copper sulfides. Certain bacteria have important and beneficial action during leaching.

Four principal methods of leaching are used in the treatment of copper ore: (1) leaching in place; (2) heap leaching; (3) leaching by percolation; and (4) leaching by agitation. The choice of method is dependent upon disposition and grade of ore to be treated as well as the character of the associated gangue. Ore bodies that contain sulfide minerals and are shattered and broken so that air and water have access to the ore are suitable for leaching in place. The copper sulfide minerals exposed are subjected to natural oxidation by alternate and intermittent contact with air and water to form water-soluble copper sulfate. The leach solution is accumulated in drainage tunnels driven under the ore body or in the lower workings of the mine. Leaching in place has been successfully applied in mines at Butte, Mont.; the Miami and Ray mines in Ariz.; the Eureka mine, Ducktown, Tenn.; the Cronebane mine, Wicklow County, Ireland; and the Aznalcollar and Rio Tinto mines in Spain. The operations of the Ohio Copper Co. at Bingham Canyon, Utah, in the early 1920's is a classical example of leaching in place at a domestic copper mine. Heap leaching is similar to leaching in place in that it depends on the natural oxidation of the sulfide minerals by continual contact with air and water. Oxide, sulfide, and mixed ores, containing some copper values but which are too low grade to be processed profitably by any other method and which must be removed to permit mining, are treated by heap leaching. The

process consists essentially of piling or dumping leaching ore, without crushing or other preparation, on an area having proper drainage to natural or prepared basins. Leach solutions are directed over the piles and allowed to drain through the heap. The sulfide minerals that have been oxidized to sulfates are dissolved in the leaching solution which collects in the prepared basins. Copper is recovered from the pregnant leach solution by cementation on scrap iron. After removal of the copper, the spent solution is returned to the piles for another cycle of leaching. Percolation leaching is another important hydrometallurgical method for recovery of copper from large deposits of low-grade ore. Ore charged to a number of leaching vats is successively treated with leaching solution, either by upward or downward percolation, or both. Usually the leach solution enters a vat at the bottom, percolates upward until the ore is flooded, is held there for a soaking period, and then drained and advanced to the next vat where the process is repeated. The flow of the leach solution in this sequence completes a single cycle. The number of cycles necessary for optimum extraction depends upon the solubility of the copper minerals in the ore. Agitation leaching is applicable to those ores that cannot be effectively treated by percolation or to those operations where efficient extraction is required at a rapid rate. Dissolution of the copper minerals is effected by keeping finely divided ore particles in suspension in the solvent. Agitation is accomplished either mechanically or by forced air and must be strong enough to prevent settling in the tanks.

Copper is recovered from leach solution by electrolysis or by precipitation with iron. The iron is usually in the form of shredded and detinned cans, detinned plate, or sponge iron. This form of precipitation is termed cementation and the copper precipitate is called cement copper.

Some copper is obtained by ammoniacal leaching of native copper ore or tailing in Michigan. In the process, the coarser native copper is recovered by gravity concentration followed by classification and separation into plus and minus 100 mesh material. Fine native copper is removed from the minus 100 mesh pulp by flotation. The plus 100 mesh sand is treated by batch, downward percolation leaching method in which cupric ammonium carbonate is the active leaching agent. An excess of ammonia is required to prevent the complex salt from hydrolyzing. The copper is recovered by simple heating to drive off the excess ammonia and the complex salt decomposes in the solution with the precipitation of copper oxide.

Smelting and Refining

Because most of the world copper production is extracted from low-grade sulfide ores that require concentration, the dominant smelting processes for recovering copper metal are adapted to treating fine-grained sulfide concentrate. The usual concentrate consists mainly of copper and iron sulfide minerals, and gangue, and the purpose of smelting is to separate copper from the iron, sulfur, and gangue. Copper's strong affinity for sulfur and its weak affinity for oxygen as compared with iron, sulfur, and other base metals in the ore form the basis for the three major steps in smelting—roasting, reverberatory furnacing, and converting.

The object of roasting sulfide ores or concentrates of copper is to oxidize sulfur and iron and to remove volatile impurities such as antimony, arsenic, and bismuth. Copper and iron sulfides are among the easiest of the common metallic sulfides to convert to oxides. Mixtures of copper and iron sulfides relatively free from inert compounds are readily ignited and will roast autogenously to 6 to 8 percent sulfur without further application of heat. However, by modern practice, the concentrate produced from some sulfide ores is controlled at the concentrator to avoid the need of roasting before reverberatory smelting. Roasters were not installed in some of the newer smelters and roasters at some of the older ones are used now as dryers. It is apparent that roasters are gradually being abandoned in copper smelting.

Roasted or unroasted materials are heated in reverberatory furnaces, which are long, room-like structures. The fuel and the charge, consisting of copper-bearing material and flux, are kept separate. Oil, gas, or pulverized coal is burned in a separate compartment from which the flame and hot gases pass over the charge. Heating of the charge is accomplished by radiation from the roof and walls rather than by direct contact with the hot gases. In this reducing or neutral atmosphere, copper and iron form the stable copper sulfide Cu_2S. Excess sulfur unites with iron to form a correspondingly stable ferrous sulfide. The two sulfides are miscible in all proportions in the liquid state and form a eutectic in the solid state. The mixture, either liquid or solid is known as copper matte. Excess iron in the form of ferrous oxide, combines with silica and enters the slag.

A few plants still use blast furnaces in smelting copper ore because they are useful under certain conditions. The feed to blast furnaces are ores more than an inch in size or fines that have been sintered. The furnace is essentially a long, narrow upright shaft. The molten

products, matte and slag, collect and are drawn off the bottom, and new material is charged at the top to keep the charge-level relatively constant. Coke is usually the fuel and is mixed with the ore and flux. A crucible is used as a collecting trough through which matte and slag flow to a forehearth or settler in which the slag rises and is removed almost continually.

Electric smelting of copper is used to produce matte where the cost of electric power is less than coal or other fuels. The chemistry of electric smelting is essentially the same as in reverberatory smelting.

Converting is the final stage in the process of smelting copper sulfide ores or concentrates and is accomplished by blowing thin streams of air through the molten matte (the product of the reverberatory or blast furnace) in a refractory-lined converter. Converting is a batch process and requires two stages.

The first or white-metal stage of converting is rapid oxidation of the iron sulfide in the matte to iron oxide and sulfur dioxide. Enough silica is supplied to form an iron silicate slag. The copper remains as copper sulfide until most of the iron has been oxidized. When slagging is complete, the slag is poured off, leaving molten copper sulfide—known as white metal at this stage. Blowing is then continued to oxidize the sulfur in the white metal leaving metallic copper. Converter slag contains 2 to 5 percent copper and is returned to the smelting furnaces for retreatment where its high iron content is generally an aid to fluxing. When the converter cycle is finished the converter is tilted to discharge the copper metal into ladles in which it is transferred to the anode furnace and casting machines. Due to the rough upper surface when solidified, the product of the converter is known as blister copper. The blister copper contains most of the precious metals and minor quantities of other elements in the charge; hence, it is refined before marketing.

Special methods of treatment are required for smelting native copper ores. Formerly, the concentrate was smelted in blast furnaces, but present output is treated almost entirely in reverberatory furnaces. The charge, consisting of concentrate, metal, coal for reducing, and if necessary limestone for flux, is fed through two holes in the top of the furnace. It takes about 24 hours to melt the charge and form slag, after which the metal is tapped into a refining furnace which is placed at a lower level.

Copper produced by smelting is too impure for most applications and requires refining before use. This crude copper is classified as blister copper produced from matte, or black copper produced from the smelting of oxidized ores or native copper ores. It contains silver and gold, and other impurities such as arsenic, antimony, bismuth, lead, selenium, tellurium, and iron. The amount of these impurities varies greatly depending upon the character of the ore and the degree of elimination in smelting and converting.

Two methods are used for refining copper, one by fire and the other by electrolysis. In general, electrolytic refining, which is more expensive, will be used when the amount of precious metals or the amount and character of the impurities present warrants. Most of the world production of primary copper, however, is processed by electrolytic refining followed by the melting of cathodes in fuel-fired reverberatory furnaces.

The fire-refining process employs oxidation, fluxing, and reduction. It is based on the weak affinity of copper for oxygen as compared with that of the impurities. Compressed air at 8 to 10 pounds pressure is introduced under the molten metal surface through iron pipes, causing a bubbling and agitating action. This exposes the molten copper to the furnace atmosphere and cuprous oxide is formed. The copper oxide dissolves in the metal bath, reacts with the copper sulfide present forming sulfur dioxide which escapes from the melt; the copper oxide also gives up its oxygen to certain impurities, forming metallic oxides which combine with added silica to form slag. Sulfur, zinc, tin, and iron are almost entirely eliminated and many other impurities are partially eliminated by oxidation. Lead, arsenic, and antimony can only be removed in large quantities by fluxing. The remaining copper oxide is reduced by partially covering the molten metal with coke and inserting green wood poles through the furnace door forcing one end below the bath surface. As fast as a pole burns away it is fed into the furnace until consumed. Reducing gases formed by combustion convert the copper oxide in the bath to copper. The progress of reduction from about 0.90 percent oxygen to the required tough-pitch content (0.02 to 0.05 percent) is determined by appearance and microscopic examination of samples. A new method of reduction using reformed natural gas has been developed by the Phelps Dodge Corp. Czechoslovakian engineers recently obtained a patent for the use of ammonia as a reducing agent in fire refining of copper.

The common sequence of electrolytic refining operations is fire refining of converter copper to produce purer and more homogeneous anodes, electrolytic refining of the anodes to recover precious metals and remove impurities, and a second fire refining to adjust the physical properties of the electrolytic copper to be cast in shapes for use in industry. In the electrolytic

refining process copper is separated from other metals and impurities by electrolytic oxidation and deposited as pure metal by electrolytic reduction in an electrolyte which is essentially a solution of copper sulfate and sulfuric acid. Anodes and cathodes are hung alternately, at carefully spaced intervals, in concrete electrolytic cells containing the electrolyte. When current is applied copper is dissolved from the anode and enters the electrolyte as $CuSO_4$ (electrolytic oxidation); at the same time an equivalent amount of copper plates out of solution on the cathode (electrolytic reduction). Many of the usual impurities—such as gold, silver, platinum group metals, and the selenides and tellurides of metals—fall to the bottom of the tank and form anode slime or mud; other impurities—arsenic, antimony, bismuth, and nickel—enter the electrolyte and necessitate close control of temperature and the copper and acid content of the electrolyte.

USES

A variety of properties are responsible for copper's important role and diversity of use in the industrial economy. Properties of copper having major significance are its high electrical and thermal conductivities, corrosion resistance, good ductility and malleability, and high strength. In addition, copper has a pleasing color, is nonmagnetic, and is easily finished by plating or lacquering; it can be welded, brazed, and soldered satisfactorily. Certain of these basic properties can be improved for many applications by alloying with other metals. As a consequence the popular commercial brasses, bronzes, copper-nickel alloys, and nickel silvers have been developed.

The use of copper and its alloys is universal. They are practically synonymous with all things electrical and have a myriad of uses in construction, autos, aircraft, missiles, railroad equipment, marine equipment, appliances, machinery and equipment, scientific instruments, utensils, jewelry, cladding, and many other applications.

Approximately half of all copper consumed is for electrical applications, including power transmission, electronics, electrical equipment, transportation, and complex weapons systems. Construction (homes, plants, office buildings) and power generation and transmission are the largest users. Virtually all building wiring is copper, as are most droplines leading from main power cables. The transmission of power continues to be a major market for copper. Although aluminum is now used for most high-voltage overhead lines, copper still dominates in high-voltage underground lines. Generation and utilization of electrical energy requires extremely large quantities of copper. Examples are heat exchangers, windings in motors, generators and transformers, magnet wire in control apparatus, and bus bars.

For communications, telephone and telegraph wire and cable are two of the biggest markets. Its excellent electrical conductivity has made copper the major metal used in the expanding applications of printed circuits. Numerous components in radio and television sets and telegraph receiving and sending equipment are made of copper or its alloys; and coaxial cables employ a substantial amount of copper. There is a large potential for the use of printed circuits in automobile instrument panels, appliances, and computers.

The noncorrosive quality of copper and its alloys accounts for many uses in construction for roofing products, plumbing goods, builders' hardware, and functional decorative applications. Sheet roofing, gutters, downspouts and heads, flashing, fittings, and accessories consume a large amount of copper. Additional architectural uses for construction and decorative purposes include balustrades, columns, doors, and screens. Copper and red brass are found frequently in plumbing items such as tank lever lift arms, toilet tank trim, lavatory fittings, tub fittings, faucets, traps and drains, flush valves, piping and tubing, and other fixtures. Brass and bronze are popular for builders' hardware because they are decorative, noncorrosive, and easy to fabricate for such items as locks, door knobs, door knockers, door stops, hinges, bolts, latches, and hasps.

The automotive industry accounts for about 9 percent of the copper consumed in the United States, using about 30 to 40 pounds per vehicle. Volume uses are in radiators, heaters and defrosters, air-conditioning units, bearings, bushings, carburetors, oil lines, strainers, wiring, switches, and plating. Major uses take strip, tube, plates, and wire; secondary uses take rods, bars, and foundry products.

The maze of wiring in the electrical systems of airplanes takes more copper than any other use in the aircraft industry. Some of the larger planes use up to 3,000 pounds of copper in the electrical systems and mechanical components.

Copper is a minor, though essential, metal in missiles. As in aircraft, the major use is in wiring systems.

Railroads use a large quantity of copper in diesel locomotives, passenger cars, and switching and signal devices. The average pullman car uses almost 2,000 pounds of copper tube in the water supply system, air brakes, heating system, air-conditioning unit, condensers, evaporator, and heating coils.

Tankers, cargo ships, pleasure craft, passenger liners, and naval vessels use copper and its alloys in a great variety of marine equipment. Naval brass is used for propeller shafting (because of its strength, torque resistance, machinability, and corrosion resistance); manganese bronze for struts and rudders (high strength and corrosion resistance); silicon bronze for fastenings and water tanks; and soft- and hard-drawn copper for exhaust yokes, fuel lines, water lines, and piping (resistance to corrosion and leaks, workability, long life). The U.S. Navy's nuclear submarines use brass in capstans, torpedo tubes, diving gear, and valves; more than 48,000 feet of copper tube in hydraulic, air, and lubricating oil lines; and cupro-nickel tube in auxiliary cooling lines, heat exchangers, lavatories, bilge pumps, and salt water service lines.

In the appliance field, manufacturers of washing machines, air-conditioning units, refrigerators, radio and television sets, and other units specify copper and its alloys for many components requiring materials that are electrically or thermally conductive, corrosion resistant, and durable.

Large machinery and equipment, turbines, and heat exchangers use copper or its alloys in many ways. Specific uses are copper for motors, other electrical equipment, and tubing; bronze for worm wheels, oil baffles, check valves, and levers; cupro-nickel for tubing; naval brass, muntz metal, and aluminum bronze for plates, sheets, bars, and weld wire.

Copper is used extensively in watches, clocks, microscopes, projectors, and many types of gages.

Solid copper, brass, and bronze are popular materials in utensils, jewelry, furnishings, and decorative items. They are used in the manufacture of such items as brass and bronze medallions; solid brass furnishings, including towel bars, curtain rods, wall hooks, and soap-dishes; cookware; table ware; and bronze and brass plaques and signs.

Products of the powder-metallurgy process have found wide usage in machine components. Compacted structural parts are used in automotive, railroad, farm, aircraft, marine, and communications equipment and in household appliances such as, washers, dryers, ironers, electric fans, and refrigerators. Metal powder of single elements, or in combination with other metals or nonmetals, are processed to make oil-impregnated porous bearings, cams, gears, motor brushes, clutch facings, contact points, filters, filaments, lock assemblies, and many other various shapes. The number of automotive applications for powder-metal parts has doubled since 1950. Iron powder mixed with copper, or copper and carbon, is used for transmission and engine parts that receive high impact and fatigue loads. Many new applications are believed feasible as powders and processing methods are designed for strength properties.

BYPRODUCTS AND COPRODUCT RELATIONSHIPS

About 98 percent of the U.S. mine production of copper is recovered from copper ore; and the remainder from complex ores. In addition to copper, important quantities of byproduct, gold, silver, sulfuric acid, molybdenum, selenium, tellurium, arsenic, and platinum-group metals are recovered. These byproducts or coproducts may be recovered at one or more of the various steps of concentration, smelting, and refining. About 27 percent of the 66 million pounds of molybdenum produced in 1963 was recovered as a byproduct largely from copper ores. About 866,000 pounds of the 928,000 pounds of selenium and 152,000 pounds of the 201,000 pounds of tellurium produced in 1963 were recovered from the electrolytic production of copper; and 358,000 tons of sulfuric acid was produced at copper plants (includes output of a lead smelter). In the 5-year period 1959–63 approximately 32 percent of the United States gold production and 28 percent of the silver production were derived from the processing of copper ores.

More than 42 percent of the copper output in Canada comes from ores of Manitoba and Ontario, mined principally for nickel, and approximately 65 percent of the world's cobalt production in 1963 came from processing Belgian Congo copper ores. It was reported that 46 percent of the molybdenum produced in the U.S.S.R. in 1959 came from copper-molybdenum ores. Some of the ores contain five times as much molybdenum as those in the

United States with the best molybdenum content.

ALTERNATE MATERIALS

Aluminum is the principal alternative material for copper as an electrical conductor. Price is one of several factors that influence its partial substitution for copper. Aluminum wire with a steel core (ACSR) has displaced copper for long-distance transmission lines. Other typical substitutions of aluminum for copper are in bus bars, fractional horsepower motor windings, and lightbulb bases. There has been an accelerated shift to the use of steel for brass in shell cases.

Aluminum and stainless steels have also somewhat reduced the use of copper in the building industry. Technology has furthered substitution for copper by the introduction of the numerous clad metals, including copper clad, which use proportionately less metal than would solid copper. Printed electrical circuits have also come into the field as a substitute for copper wire and plastic tubing replaces copper in some automobiles and appliances and other uses.

SECONDARY SOURCES AND RECOVERY

Secondary copper is recovered from copper scrap, copper-alloy scrap, and other copper-bearing scrap materials. The term includes refined copper or the copper content of copper-base alloys, copper-bearing alloys, chemicals, and compounds. Although some brass is smelted for the separate recovery of its copper content, a large percentage of reclaimed brass is remelted into brass ingots that are sold as brass in the secondary market. The copper content of the scrap substitutes for primary copper in industrial and commercial products and thus may be classed as secondary copper.

Secondary copper is recovered from two principal classes of scrap, old scrap and new scrap. However, only old scrap is available from the accumulating reserve of secondary copper through reclamation of copper, brass, bronze, and other alloy products that have been used and then discarded because they are obsolete, worn out, or damaged. Such articles are wire, fired cartridge cases, pipe, automobile radiators, bearings, valves, screening, and lithographers' plates. Old scrap is collected by several thousand dealers who for the most part are not affiliated with primary copper producers.

The new scrap generated in fabricating and manufacturing semifinished and finished products from primary copper and copper-base alloy forms does not form a reservoir supply to supplement the production of primary copper. Examples of new scrap are defective castings, clippings, punchings, turnings, borings, skimming, drosses, and slag. Such scrap represents a circulating quantity of copper previously accounted for as supply of primary copper and returned to the fabricating process without reaching the product stage. However, data on the movement of new scrap have significance as indicators of business activity in the fabricating and scrap reclamation industries.

Channels through which much of the reclaimed copper returns to industry from scrap dealers and fabricators are brass mills, brass and bronze ingot makers, secondary and primary smelters and refiners, and foundries.

Total secondary copper production in 1938 was slightly less than 500,000 tons. By 1943 production had more than doubled and the all-time peak of 1,100,000 tons was attained. From then through 1958 output was relatively uniform and averaged 905,000 tons a year. Production declined to 849,000 tons in 1961 and rose to 974,000 tons in 1963.

More than two-thirds of the secondary copper is recovered in alloys, principally in ingots of brass and bronze, with lesser quantities alloyed with aluminum, iron and steel, and other metals. Most of the remainder of the annual output is recovered as refined copper, copper powder, and castings. Approximately 1 percent of the secondary copper output is in chemical compounds.

Copper and copper-base alloy scrap is sorted and separated into its various classifications. The separation is made on the basis of color, hardness, magnetic properties, type of fabrication, reaction to acids and other reagents, and original source. Brass scrap is sorted piece by piece. Like materials are grouped, assayed, and stored according to composition and metallic content. Furnace charges are made up of weighted amounts of one or more types of scrap that will closely approximate the desired composition of the alloy to be cast. After the charge has been melted a sample of the bath is taken and refining, consisting of fluxing, oxidation and slagging is started. After refining calculated additions of virgin metals are made to adjust the analysis of the melt to specifications and the heat is tapped and poured into ingots.

A substantial quantity of clean copper scrap is remelted, cast into anodes, and electrolytically refined. Other copper scrap is charged to reverberatories at primary smelters and is recovered as electrolytic or fire refined copper.

The major uses of copper in the principal foreign consuming countries are about the same as

those in the United States with a similar relationship between consumption of scrap and total copper. Further, scrap is collected, marketed, and processed in foreign countries in much the same manner as it is in the United States. This is particularly true in Europe where 40 to 45 percent of the world copper is consumed, principally in Great Britain, West Germany, U.S.S.R., France, and Italy. By applying the ratio of world-to-U.S. consumption for the period 1908–63 to the resource pool as developed for the United States, the secondary resource pool for the world is estimated to be approximately 90 million tons.

TABLE 3.—*Secondary copper produced in the United States*

[Short tons]

	1954–58 (average)	1959	1960	1961	1962	1963

[1] Includes copper in chemicals, as follows: 1954–58 (average), 14,485; 1959, 10,061; 1960, 12,714; 1961, 10,708; 1962, 9,986; and 1963, 10,191.

RESERVES

Although the world is plentifully endowed with copper, the six principal producing areas contain 85 percent of the world measured and indicated reserve. In order of the magnitude of reserves these are the western slope of the Andes in Chile and Peru, the central African copper belt in Northern Rhodesia and the Republic of the Congo, the Western United States, the Ural Mountains and the Kazakstan region in the U.S.S.R., the Precambrian area of central Canada, and the Lake Superior region of North America. New discoveries and development of extensions of known deposits during the last decade increased the known copper resources. The measured and indicated world reserve, in terms of metal content, is estimated to be 212 million tons of copper. The estimates are based on the assumption that the cost price ratio will be such as to permit mining ore having approximately the same grade as that now being produced.

The reserves of selected countries are—

Country	*Ore reserves copper content (thousand short tons)*
Australia	1,200
Canada	8,400
Chile	46,000
Mainland China	3,000
Republic of the Congo	20,000
Japan	1,200
Peru	12,500
Republic of the Philippines	1,000
Poland	11,400
Northern Rhodesia	25,000
Spain	4,500
United States	32,500
U.S.S.R.	35,000
Yugoslavia	2,700

Reserves in Bolivia, Cuba, Cyprus, Finland, India, Mexico, Norway, Sweden, Turkey, and other countries total about 7.5 million tons. The extension of mine workings and delineation of new deposits by planned expansion and exploration projects will change substantial inferred reserves into measured and indicated ore.

An important part of the reserve is the ever-increasing reservoir of secondary copper which is being created and is capable of providing for about one-third of the Nation's requirement. There is no statistical series showing the amount of copper consumed in end-use items that would indicate the quantity in service in nondissipative use. However, assuming that three-fourths of the new copper is consumed in the manufacture of reclaimable products, it is estimated that the reserve of recoverable copper in use in the United States exceeds 35 million tons.

CONSERVATION

Mining and metallurgical research leading to more economic extraction and beneficiation of copper ores have made immense tonnages of ore available which otherwise would have been of no value as a source of copper. The need for lower costs, in turn, has encouraged research for the development of more efficient methods and techniques at all levels in the production of copper and copper products.

One of the most effective conservation practices is the reclamation of copper from scrap that provides approximately one-fourth of the U.S. supply. Another noteworthy conservation practice is the recovery by leaching of copper from material too low-grade or with a minera-

logical content unsuitable for concentration. Native copper is also recovered by reworking old tailing from gravity concentration, flotation, and leaching.

SOURCES OF STATISTICAL INFORMATION

Monthly and annual data on mine production of recoverable copper are reported by producers to the Federal Bureau of Mines; monthly data on production of blister copper, refined copper by shapes, stocks of blister, and refined and unrefined copper are reported by the primary smelting and refining companies. Primary copper plants and chemical establishments report stocks, production, consumption, and shipments of copper sulfate monthly, and copper smelters report production of byproduct sulfuric acid annually. Sales of copper by copper-selling agencies are reported annually.

Consumption of refined copper by major industry classes is reported monthly. Consumption of scrap by types, by primary copper producers, secondary smelters, and brass mills is reported monthly. Other consumption data collected annually include consumption of brass and bronze ingot by foundries, and refined copper and scrap at foundries, miscellaneous manufacturers, and chemical plants. The domestic data collected are sufficiently adequate and accurate for current programing and planning. However, data on consumption of copper by end uses and geographic locations are not available. Also, the Bureau of Mines does not gather data on consumption outside the United States.

World mine and smelter production data are compiled by the Bureau's Division of International Activities. U.S. imports and exports of copper are obtained by the Bureau of the Census.

Statistical information on world production and consumption is published by the American Bureau of Metal Statistics and the British Bureau of Nonferrous Metal Statistics.

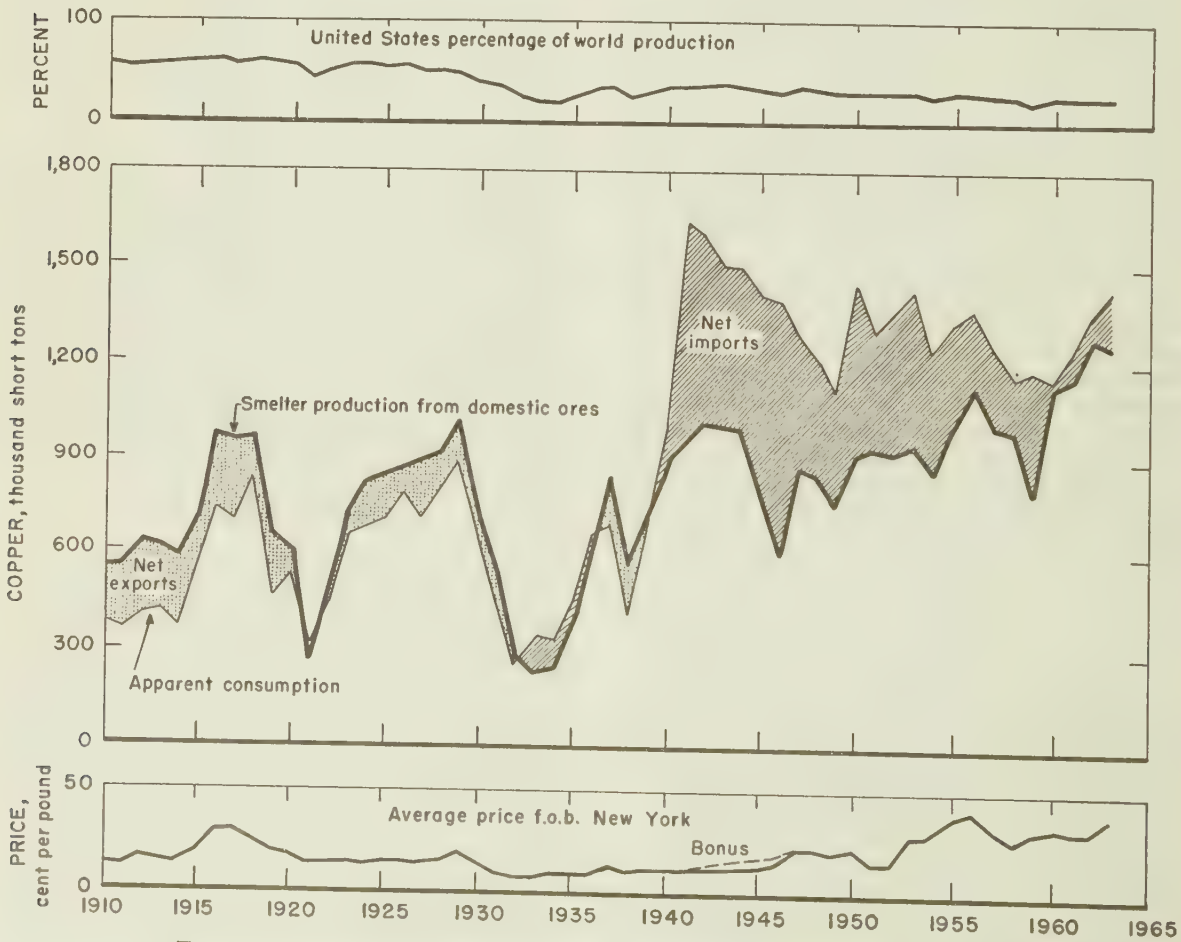

FIGURE 1.—Production, Consumption, and Price of Copper in the United States.

PRODUCTION, CONSUMPTION, AND TRADE

Production

World mine production of copper climbed steadily from 3.1 million tons in 1954 to a record of 5.2 million tons in 1963. The increased rates were attributed mainly to new properties attaining production schedules and established mines producing at accelerated rates, conditions that were encouraged by strong demand and high prices quite free from pronounced fluctuations.

The United States has been the largest copper-producing country for many years (figure 1). It lost this position only once since 1883, when Chile outranked it in 1934, a depression year. However, the percentage of world production produced in the United States has declined from about 52 percent in 1926 to 23 percent in 1963.

Consumption

Annual consumption of copper in the world increased from 4,369,000 tons in 1959 to 5,315,000 tons in 1963, an increase of about 22 percent, according to data compiled by the American Bureau of Metal Statistics. Comparable data for the previous 5-year period were 3,482,000 tons in 1954 and 4,075,000 tons in 1958, an increase of 17 percent. The rise in consumption in the last decade is attributed to growth of industry and electrification in developing nations and accelerated expansion of industrial activities in others. The United States continued to be the largest copper-consuming country in the world, accounting for about 30 percent of the total world consumption in 1963. Estimates of consumption in the U.S.S.R. placed it in second place in 1962 and 1963 with about 12 percent of the total for each year. Consumption of copper in the United Kingdom reached a high in 1960 when the country was in second place with about 13 percent of the total consumption. Thereafter consumption in the United Kingdom declined through 1962 and although use rose in 1963 the country remained in third place with less than 12 percent of the total. Use of copper in the Federal Republic of Germany reached a peak in 1961 when the country was in second place, consuming 12 percent of the world total. Thereafter use declined and by 1963, the country was in fourth place with about 10 percent of the total. Consumption increased in Japan by 40 percent from 1959 to 1963 and use rose about 30 percent in Canada during the same years.

Consumption of refined copper in the United States rose almost 20 percent from 1959 to 1963 when a record high of 1,744,000 tons were used. There are no recent continuing statistical data showing the consumption of copper by end uses. However, percentages of the total consumption in 1960 by industrial and other uses, prepared by a large producer of copper, are shown in table 2. The pattern of major uses of refined copper by broad industry classifications (table 8) remained virtually unchanged from 1959 to 1963. Average consumption for the 5 years at wire mills was 58 percent of the total and at brass mills was 39 percent.

Trade

The United States is the leading country in the world trade of copper. Crude materials, such as ores, concentrates, matte, and blister, as well as refined copper are imported. Refined copper and fabricated copper, fabricated-copper products, and manufactured goods containing copper are exported. The other leading producing countries—Canada, Chile, Northern Rhodesia, Peru, and the Congo (Léopoldville)—export most of their output. West Germany and the United Kingdom regularly import most of their requirements.

Except for a few years after World War I and during the depression of the thirties, U.S. production of copper exceeded domestic demand and there was a substantial surplus for export. World War II disturbed the balanced trade through which smelting, refining, and fabricating facilities of this country were used to treat foreign crude materials while refined copper and manufactures of the metal were returned abroad. After the beginning of the war, the United States needed all the copper produced in the country and imported it to fill the large armament requirements. The high level of industrial activity after the war continued to require large supplies of copper, much of which was met by importations. The alltime record high for imports was reached in 1945 when receipts of all unmanufactured copper totaled 853,000 tons and a record of quantity of refined copper (531,000 tons) was received. The outbreak of war in Korea in June 1950 again made large imports of copper necessary. Imports met about one-fourth of the U.S. requirements until 1959. Exports exceeded imports in 1960 for the first time in 20 years. The United States returned to a net importing nation in 1962 and this condition became even more pronounced in 1963. From 1959 through 1963, 44 percent of the imports of unmanufactured copper came from Chile and 19 percent from Canada. Imports from Peru averaged 15 percent of the 1959–63 total as a result of increased production in the country from 1959 onward.

[1] Includes scrap.
[2] Smelter output from domestic and foreign ores, exclusive of scrap. Production from domestic ores only, exclusive of scrap, was as follows: 1954–58 (average), 1,006,649 short tons; 1959, 799,329; 1960, 1,142,848; 1961, 1,162,480; 1962, 1,282,126; and 1963, 1,258,126.

TABLE 8.—*Refined copper consumed by classes of consumers in the United States*

[Short tons]

Year	Wire mills	Brass mills	Chemical plants	Secondary smelters	Foundries and miscellaneous	Total
1954–58 (average)	771,950	563,450	1,642	7,395	31,748	1,376,185
1959	836,177	584,100	794	8,111	33,849	1,463,031
1960	828,823	486,460	1,036	8,206	25,371	1,349,896
1961	823,799	599,765	1,269	9,504	28,493	1,462,830
1962	922,908	636,149	1,488	9,460	29,671	1,599,676
1963	1,036,162	673,907	1,238	3,652	29,314	1,744,273

Imports from the Republic of South Africa with 6 percent of the total exceeded those from both Mexico (5 percent) and the Rhodesia and Nyasaland (3 percent). Receipts of blister and other unrefined copper totaled 63 percent, refined copper 25 percent, and ore and concentrate 11 percent.

Most of the copper exported from the United States is refined copper and in advanced forms of manufacture, in which the copper content is not calculable. Exports of copper were under control from World War II until September 1956 because supplies in the United States were inadequate to fill requirements. After removal of restrictions on exports, shipments increased yearly (except for 1959) until 1960 when 510,000 tons were exported, only 5,000 tons less than the all time record in 1917. Exports declined annually after 1960 and 345,000 tons was shipped in 1963. Shipments of refined copper, the principal export class, in 1959–63 averaged 334,000 tons.

Much of the output of copper in Canada is exported in various forms and shipments of unmanufactured material totaled 316,000 tons in 1963. Japan received about 62 percent of the copper content in exported ores, concentrates, and matte; the United States and Norway each received about 17 percent. The United Kingdom and the United States received about 46 percent and 34 percent, respectively, of the 215,000 tons of ingots, bars, and billets exported in 1963. Much of the remainder was shipped to France, India, and West Germany.

Most of Chile's output is exported as refined and blister copper. The United States receives 40 percent of the exports, principally as blister copper; the United Kingdom imports 20 percent, about two-thirds of which is refined metal. Of the 188,300 tons of copper exported from Peru in 1962, 69 percent was blister copper, 22 percent refined, and 9 percent ore and concentrate. The United States received 41 percent

of the exports; the United Kingdom and West Germany each imported 18 percent.

More unwrought copper was exported from Northern Rhodesia than from any other country during 1959–63. Exports of refined and blister copper reached a peak of 633,300 tons in 1963. During the 5 years under review, the United Kingdom received most of the shipments and West Germany was in second place.

Belgium is the principal destination of copper exported from the Congo (Léopoldville). Substantial quantities were shipped to Beira and Lobito depots, but it is thought that most of this copper was shipped ultimately to Belgium.

Imports of all classes of copper are an important segment of the supply of Japan. Imports of ore and concentrate rose from 370,000 tons in 1959 to 623,000 tons in 1963, with receipts reported from 43 countries. Shipments from Canada rose from 15,000 tons to 234,000 tons and those from the Philippines averaged 194,000 tons for the 5 years. Receipts of unwrought copper increased from 15,900 tons in 1959 to 115,000 tons in 1961 and declined to 52,000 tons by 1963. A large percentage of the unwrought copper was received from the United States.

Tariff

An excise tax of 4 cents per pound was imposed on copper June 21, 1932. The Government was virtually the only importer in World War II, and during the period it held this position the tax was not applicable. The tax was reinstated for a very brief period, following which it was suspended by acts of Congress from April 30, 1947, to June 30, 1950. The suspended tax, meanwhile, was reduced as a result of the Trade Agreement negotiations at Geneva in 1947, to 2 cents per pound effective March 16, 1949. The 2-cent tax came into effect on July 1, 1950, but was suspended again on April 1, 1951. The law provided that the Tariff Commission must notify the President within 15 days after the end of any calendar

Source: Bureau of Census.

month in which the average price dropped below 24 cents per pound, delivered Connecticut Valley, and within 20 days thereafter the President would revoke the suspension. The suspension was extended each year until 1955 when it was extended to June 30, 1958. Meanwhile, at the June 1956 meetings in Geneva on General Agreements Tariffs and Trade (GATT), copper was subjected to certain concessions. The excise tax on copper metal, ores, and concentrates would drop 15 percent (5 percent for each of 3 years) if the tariff were reimposed and the price of copper was not below 24 cents per pound. For fiscal 1957, 1958, and 1959, the excise tax would be 1.9, 1.8, and 1.7 cents, respectively. The latter tax became effective July 1, 1958. As the price of copper was above 24 cents per pound from July 1958 through 1963, the 1.7-cent-per-pound excise tax was applicable to imported copper throughout this time.

STRATEGIC CONSIDERATIONS

Self-Sufficiency

Prior to 1940 the United States was a net exporter of copper. Since that time, because of World War II and postwar demands, a substantial portion of the Nation's copper supply has been imported except for the years 1958, 1960, and 1961. The largest quantities were imported during World War II, the peak year being 1945 when net imports reached 721,000 tons. From 1946 through 1956 copper in unmanufactured forms received from foreign sources ranged from 200,000 to 500,000 tons per year. In 1957 and 1958, demand and imports decreased. A prolonged strike in 1959 caused a substantial loss of domestic production and created the need for a larger quantity of net imports. In 1960 imports and exports were almost equal and in 1961 the United States again became a net exporter. The United States returned to a net importing nation in 1962 and net imports in 1963 totaled almost 200,000 tons.

For the short term, the U.S. position with respect to an adequate supply of copper is satisfactory. This outlook is supported by an estimated annual mine production capacity of 1.5 million tons of copper; vigorous exploration, development, and expansion programs for increasing the output; an annual availability from second sources (old scrap only) of from 450,000 to 500,000 tons; and a reserve of 1,122,000 tons of copper in the national stockpile. Furthermore, expansion of copper production in Canada, Chile, and Peru provides ample sources of imports in the Western Hemisphere. However, increasing competition by foreign interests for the world supply of copper is encroaching on the U.S. supply from these nations.

TABLE 11.—*United States mine production of copper, apparent consumption of new copper and excess consumption over production*

[Thousand short tons]

Period	Mine production	Apparent consumption (new)	Excess consumption over production
1920–29 (average)	7,299	6,499	[1] 800
1930–39 (average)	5,023	4,919	[1] 104
1940–49 (average)	8,796	13,642	4,846
1950	909	1,447	538
1951	928	1,304	376
1952	925	1,360	435
1953	926	1,435	509
1954	835	1,235	400
1955	999	1,336	337
1956	1,104	1,367	263
1957	1,087	1,239	152
1958	979	1,157	178
1959	825	1,183	358
1960	1,080	1,148	68
1961	1,165	1,237	72
1962	1,228	1,352	124
1963	1,213	1,423	210

[1] Production excess.

Stockpiling

Copper is stockpiled under the authorizations of several statutes. The Strategic and Critical Materials Stockpiling Act of 1946 (Public Law 520) (a revision of Public Law 117 passed by the 76th Congress in 1939), provides for the acquisition and retention of stocks of strategic and critical materials and to encourage the conservation and development of sources of these materials within the United States, and thereby decrease and prevent whenever possible a dangerous and costly dependence of the United States upon foreign nations for supplies of these materials in times of national emergency. The Defense Production Act of 1950 authorized the Government to encourage expansion of productive capacity and supply by purchasing materials for Government use or resale. The reserve thus accumulated is referred to as the "DPA" inventory or stockpile. The Supplemental Stockpile was authorized by the Agricultural Trade Development and Assistance Act of 1954 (Public Law 480, 83d Congress), and materials acquired by the Department of Agriculture in exchange for surplus agricultural commodities that deteriorate and are costly to store are placed in this inventory. The "CCC" (Commodity Credit Corporation) inventory is acquired by the Department of Agriculture by barter of surplus agricultural commodities. If there is no Government use for the material, they are required by law to be transferred to the supplemental stockpile.

The status of Government stocks of copper on June 30, 1964, in thousand short tons was:

Grade	Strategic stockpile	DPA	CCC	Supplemental	Total	Maximum objective
Stockpile grade	1,008	96	-------	11	1,115	775

Industry Concentration

Sixteen of the 25 leading copper-producing mines in the United States are in Arizona and together produced 54 percent of the domestic output in 1963. A mine in Utah produced 17 percent, mines in one district in Montana and another in New Mexico produced 6 percent and 7 percent, respectively. Nevada's contribution of 7 percent was divided between two districts, one in the eastern part of the State and the other in the western part. Michigan supplied about 6 percent of the total from two areas on the Upper Peninsula and Tennessee contributed 1 percent from one locality. The ore was processed by milling or leaching facilities near the mines and most of the products of these plants were smelted at nearby establishments. Of the 8,600,000 rated annual smelter charge capacity (ore plus flux), 47 percent is located at eight smelters in Arizona. A smelter in Utah represents 14 percent of the total capacity and a plant in Montana 12 percent. A smelter in Washington has 7 percent of the total and three smelters in Nevada, New Mexico, and Texas each have 5 percent. Smelters in Michigan contribute 2 percent as does one in New Jersey and a smelter in Tennessee accounts for 1 percent.

Electrolytic refineries in the United States have a rated annual capacity of 1.96 million tons, of which 59 percent is in five refineries situated on the eastern seaboard as follows, New Jersey 30 percent of the total, Maryland 20 percent, and New York 9 percent. Other States and percentages of capacity are: Texas, 15 percent; Utah, 11 percent; Montana, 8 percent; Washington, 5 percent; Arizona and Missouri, 1 percent each. Three refineries that have an annual rated capacity of 137,000 tons of Lake copper are located in Michigan. A refinery in New Jersey, which also produces electrolytic copper, has 53 percent of the annual capacity of the fire refining in the United States. A refinery in New Mexico has 34 percent of the capacity and another in Texas, 11 percent.

Vulnerability of Supply

Much of the world's supply of copper is produced in major producing areas affected by social and political instability. Furthermore, a large proportion of the copper is transported from the country of origin to areas of consumption over long sealanes sometimes linked with overland routes through other emerging nations. Historically, imports meet about one-fourth of the U.S. demand for copper. Chile and Peru supplied 59 percent of the imports in 1963 and a large percentage of the receipts was blister. This supply is made vulnerable by ocean transportation and more than 60 days are required for shipping and refining. About 15 percent of the imports came from Africa and about two-thirds of the receipts were blister. Because they are confronted with much longer overland and ocean supply lines, exports from Africa are relatively more vulnerable and the time consumed by shipments from the source to market is greater than for receipts from South America.

GOVERNMENT PROGRAMS

Under the Defense Production Act of 1950, as amended, various types of production expansion assistance were developed for copper—production loans, Government floor-price purchase contracts with escalation provisions, certificates of necessity permitting accelerated amortization of capital investment for income tax purposes, and exploration loans amounting to 50 percent of total costs repayable from eventual production. The San Manuel Copper Corp. and the White Pine Copper Co. started delivering their production to the Government under the Defense Materials Procurement Agency (DMPA) floor-price contracts in the last quarter of 1957 after the price of copper had fallen to 27 cents in September. Copper reserves were developed in several areas as a result of exploratory work under the Defense Minerals Exploration Administration (DMEA) program.

Other defense measures were establishment of ceiling prices of copper and copper alloys and strict export controls. Early in 1953 the situation had eased to the point where price controls and national and international allocations of copper were abandoned although military and Atomic Energy Commission needs were still to receive preferential treatment. Due to the continuing shortage of copper until the middle of 1956, quantity export controls were maintained on copper through the third quarter of 1956 and on copper scrap through the third quarter of 1957.

Effective November 10, 1958, copper items, including ores, concentrates, etc., refined copper, copper scrap, and copper-base scrap, were removed from the U.S. Department of Com-

merce positive list (requiring export licenses) and placed on the general list for export to all destinations except Hong Kong, Macao, and the Communist nations. Effective February 20, 1959, the U.S. Department of Commerce reimposed controls on all copper exports; shippers were required to declare destinations of all shipments except those to Canada.

Copper was removed July 1, 1962, from the list of materials eligible for assistance through OME in the financial risk of exploratory ventures judged capable of increasing the Nation's resources of selected minerals.

PRICES AND COSTS

Average annual copper prices in the United States have ranged from 5.67 cents per pound in 1932, the lowest on record, to a peak of 41.88 cents in 1956. Under price control during World War II and for a short period thereafter when the Government granted premiums on a quota system for copper production, February 1942 to June 1947, the average price including all premiums was 14.3 cents per pound. Government regulation of prices following the outbreak of war in Korea established a ceiling of 24.5 cents per pound on January 26, 1951, which lasted until copper prices were decontrolled February 25, 1953. Labor strikes in the latter half of 1954 and increasing consumption of copper both in the United States and Europe resulted in a shortage of copper, and the price rose continually reaching 46 cents per pound on February 21, 1956, the highest in 90 years. Supply surpassed demand in the United States early in 1956 and the first reduction in price in more than 2 years was made in July of that year. A continuing high rate of production and declining consumption resulted in increasing stocks and the price of copper declined gradually until it reached a low of 25 cents per pound in January 1958. The price was raised to 26½ cents in July and to 29 cents in October.

Primary producers' price for electrolytic copper delivered was established at 33 cents per pound in November 1959 and remained unchanged until October 1960. On that date, cumulative effects of increased output slackened demand and large consumer inventories caused a 3-cent-per-pound drop to 30 cents. The price of copper declined in early 1961 to 29 cents per pound but rose to 31 cents by the middle of May. Primary producers' price for copper remained unchanged at 31 cents per pound through 1963, the longest period of price stability except when under Government control.

Information on operational or overall costs per unit of production or of final product for mining, milling, smelting, refining, marketing, etc., is not readily available. Costs of producing copper in the free world vary widely from country to country and from mine to mine. A study by the Rhodesian Selection Trust Ltd., indicated the cost of producing electrolytic copper in 1955 in the Northern Rhodesian Copperbelt was over 19 cents per pound compared with an average of about 18.25 cents per pound within the United States. An analysis of 1956 production in the United States by The Anaconda Company showed that 13.9 percent cost 30 cents per pound or more, 22.6 percent 29 cents or more, and 33.1 percent 25 cents or more, leaving a balance of 66.9 percent produced under 25 cents per pound, but implying the overall average cost per pound of copper in the United States exceeded that of foreign production. Another statistical study arrived at a 5-year (1954–58) cost of approximately 25 cents per pound for seven domestic and foreign producing companies that accounted for 30 percent of the world's mine production. A more recent study indicated that the median cost for 1960–62 has been in the bracket of 17½ cents to 20 cents per pound, a rise of 2½ cents over costs in the 1950's.

TABLE 12.—*Average prices of electrolytic copper*

[Cents per pound]

Year	Domestic f.o.b. refinery [1]	Domestic f.o.b. refinery [2]	Domestic copper delivered
1959	30.82	31.182	30.7
1960	32.16	32.053	32.1
1961	30.14	29.921	30.0
1962	30.82	30.600	30.8
1963	30.82	30.600	30.8

TAXES

The Federal Government and a few of the State governments levy taxes on incomes of copper-producing corporations. In most States, property or ad valorem taxes on the value of mineral or surface facilities and severance taxes are levied to provide revenues for counties, municipalities, and school districts.

Corporations producing copper are subject to the corporate income tax rates which consist of a normal tax of 30 percent on the total amount of taxable income and a surtax of 22 percent on taxable income in excess of $25,000. Generally taxable income is gross income less the actual monetary costs of producing that income. However, the tax law contains several special provisions regarding income derived from mineral

deposits (natural resources). In recognition of the wasting character of mineral deposits, a special deduction, known as percentage depletion, is allowed which may have no relationship to actual costs. In addition, the tax law provides special treatment for certain capital expenses incurred in finding and preparing mineral deposits for production. Producers are granted a depletion allowance of 15 percent on domestic and foreign production.

Property tax base varies from State to State and in some instances it differs in certain sections of a State. The basis for taxation of property in some States is present worth, in others it is net proceeds, and a few States use both. In Michigan, mining plants and equipment are exempt from taxation but ore bodies are carefully appraised for present worth. In Tennessee only real estate and plant facilities are subject to property tax.

Severance taxes, like royalties, are based on gross production. A true severance tax is one measured by applying a specific rate per unit (ton, pound) to the total quantity produced. Four of the major copper-producing States are recorded as imposing severance taxes; however, Arizona's is classified as a sales tax, Montana's is called a mine metal license, and Utah's is known as an occupational tax. These all are collected whether or not a profit is realized from the operation of producing, and therefore are rightfully considered severance taxes. New Mexico levies a severance tax and a sales tax, which is essentially another severance tax.

EMPLOYMENT AND PRODUCTIVITY

Employment

The working force of the copper industry engaged in mining and beneficiating ores, smelting concentrates, and refining copper has remained relatively steady since World War II, averaging approximately 33,000 men annually and ranging from a low of 29,000 in 1946 to a high of 37,000 in 1956. The average number of men employed daily in 1963 was 29,600. About half were engaged in mining, one-sixth in milling, and a third in smelting and refining. This distribution has been fairly uniform throughout the postwar years with increases and decreases of employment in all operations following the accelerated or relaxed industrial activity of the country.

The years of highest employment at copper mines were 1916 and 1917, slightly more than 61,000 men mined a little over 1 million tons of recoverable copper in 1916 and just under 1 million tons in 1917. In 1929 it took 37,000 men to mine 1 million tons; in 1942, and 1943, 23,500; in 1956 and 1957, 18,000; and in 1963, 11,800. This decrease in employment requirements is due to the adoption of mass mining and milling methods which require fewer production workers. The widespread mechanization and large-scale operations have changed the number of men and the types of skills needed. Men now are trained for specific tasks and less dependence is placed on the worker's mining skills. Mining is directed and supervised by experienced foremen in accordance with plans prepared by technically trained mine superintendents and engineers. Mechanization has increased the demand for mechanics, enginemen, technicians, and operators of many kinds of machines while eliminating a large number of unskilled laborers.

Productivity

Over the last 50 years the annual rate of domestic mine production of copper has more than doubled and the ore mined per year increased almost fourfold, while man-hours assigned to copper mining has declined by two-thirds. In 1914, 103 million man-hours were required to produce 36 million tons of ore containing 574,000 tons of copper, whereas in 1963, 35 million man-hours produced 146 million tons of ore yielding 1.21 million tons of copper. Converting this information into productivity terms, 0.35 tons of ore and 11.1 pounds of metal were produced per man-hour in 1914 as compared with 4.17 tons of ore and 69.3 pounds of copper per man-hour in 1963. The rise in productivity is due to the greater proportion of copper ore mined by open pit and highly productive, large-scale underground methods plus technological advances in mining processes and equipment.

Productivity in ore concentration plants may be measured by man-hours of labor per ton of ore milled. In the last two decades the amount of ore milled increased 60 percent while the average number of men working daily decreased 27 percent. In 1944, 18 million man-hours were used while processing 86 million tons of ore from which 814,000 tons of copper were recovered, whereas in 1963, 12 million man-hours were required in concentrating 141 million tons of ore, yielding 1.02 million tons of copper. Converting this information to productivity terms, 4.8 tons of ore was processed and 90.0 pounds of copper was produced per man-hour in 1944 compared with 12.1 tons of ore and 174.3 pounds of metal in 1963. Significant proportions of the increased efficiencies at new and enlarged concentrators are due to technological advances made in new equipment and automation resulting in treatment of larger tonnages by fewer men.

Data are not readily available on productivity at smelters and refineries principally because the number of workers and man-hours are not reported separately for smelters and refineries. Employment and man-hours worked at these establishments are relatively consistant and changes in productivity are caused by varying production quantities. Foreign materials account for about 25 percent of refinery output but foreign ores are a small percentage of domestic smelter charges. Therefore, man-hours worked at smelters and refineries have been matched with smelter output from domestic ores for the following productivity expressions of pounds of copper per man-hour. In the last 20 years employment at smelters and refineries averaged 11,200 men with a low of 7,700 in 1944 and a high of 12,400 in 1947. An annual average of 28.8 million man-hours were expended in producing an average of 912,000 tons of copper. The average production of copper during the 20 years was 63.3 pounds of copper per man-hour, ranging from a low of 50.9 pounds in 1946 to a high of 93.8 pounds in 1959. Improvements in smelting and refining processes that have increased productivity at smelters and refineries in the last few years are elimination of roasting at some smelters; larger reverberatory furnaces; deoxidation of converter copper by gas; improved methods for casting anodes, wire bars, cakes, and billets; and continuous casting at refineries.

TRANSPORTATION

Ore from surface mines in the United States is transported to concentrators by captive or privately owned standard gage railroads, trucks of large capacity, skipways, conveyor belts, or combinations of these facilities. Large underground mines have highly developed transportation systems consisting of rail haulage and hoisting facilities or shuttle cars and conveyor belts. Transportation of concentrate to smelters is by conveyor if the smelter is near the concentrator, or by railroad and/or large capacity trucks to more distant reduction works. Where a refinery is near or integrated with a smelter, unrefined copper is moved for refining by rail or by other methods such as crane and ladle.

In Chile and Peru, concentrate is smelted near the concentrators or moved to smelters by railroad only or combined with aerial tramway or pipeline. Smelter and refinery products for export are transported by rail to ports not too distant. Steamship distances from Valparaiso (Chile) to New York, Liverpool, and Hamburg are 5,300, 8,300, and 8,900 miles, respectively. Copper exported from Chile and Peru accounts for most of that metal shipped through the Panama Canal. Overall shipments through the Panama Canal are as follows (in thousand tons):

Origin	Destination	1959	1960	1961	1962	1963
South America, west coast.	U.S. east coast:					
	Copper (metal).	221	248	280	309	268
	Ore	25	36	32	37	19
Do	Europe:					
	Copper (metal).	318	373	426	427	395
	Ore	92	53	62	54	107
U.S. west coast	Europe: Copper (metal).	27	16	56	48	40
West Indies	Asia: Ore	7	6	10	11	12

Note: Does not include small shipments of undifferentiated metals.

Copper is transported from the Congo (Léopoldville) over three routes. The route between Elisabethville and the port of Matadi is entirely within the nation. Shipments are by rail to Port Franqui on the Kasai River, thence by the Kasai and Congo Rivers to Léopoldville where they are transferred to a railroad connecting with Matadi. The other routes are by railroad through either Angola (Portuguese) to the port of Lobito or through Northern and Southern Rhodesia and Mozambique (Portuguese) to the ports of Beira or Lourenco Marques. Most of the copper exported from Northern Rhodesia is shipped over the same railroads to Lobito, Beira, or Lourenco Marques.

Approximate distances between some shipping points in Africa are:

From	To	Miles
Elisabethville, Congo (Léopoldville).	Port Franqui, Congo	900
	Beira, Mozambique	1,600
	Lourenco Marques, Mozambique.	1,612
	Lobito, Angola	1,309
Port Franqui, Congo (Léopoldville).	Léopoldville, Congo	500
Léopoldville, Congo (Léopoldville).	Matadi, Congo	300
N'dola, Northern Rhodesia	Beira, Mozambique	1,446
	Lourenco Marques, Mozambique.	1,478
	Lobito, Angola	1,449

RESEARCH

Tremendous reserves of copper have been developed in recent years by extensive exploration projects in all the major producing countries. As a result, ore reserves in the principal copper-producing areas today substantially exceed those in the past. The increase has resulted from exploring new discoveries, reappraising idle mining districts, and developing inferred extensions of known deposits. In-

tensive engineering and geologic investigations and exploratory drilling, often supplementing geochemical and geophysical surveys, were used when exploring the deposits. Results of these exploratory programs often are verified by underground work which also yields large samples for metallurgical testing. New techniques using statistical analyses and computer programs have been developed to evaluate the results of exploration.

Manufacturing companies have done much to improve efficiencies and control costs by developing more efficient earthmoving and transporting machines. Drilling procedures have been improved by studies of drilling techniques and sizes and spacing of blast-drill holes. Introduction of ammonium nitrate-fuel oil explosives (ANFO) contributed to a reduction of blasting costs.

Most segments of the industry have research facilities and men charged with experimentally investigating methods, technologies, and equipment in their particular field. These studies are supplemented by research programs of the Federal Government and institutions such as foundations, associations, and colleges or universities. Attention has been directed in mining to ground stabilization, open-pit design, and development of equipment and procedures for determining stress relief in rock as mining progresses. Refinements in concentration have resulted from continuous research in methods and equipment for crushing, grinding, classification, and flotation. Studies of the recovery of copper from refractory ores by roasting ore, halide salt, and carbonaceous material have yielded encouraging results. Application of biological science to extractive metallurgy has been investigated. Research has indicated that nonpyritic smelting of native copper is feasible by substitution of other sources of sulfur, such as gypsum, for pyrite. The fabricating industry is widening its market research activities in traditional fields as well as in new areas.

The Copper Development Association was organized in 1963 with a membership that included copper mining companies, smelting and refining firms, fabricating mills, and foundries. The new group assumed responsibility of practically all the activities of the Copper and Brass Research Association which ceased operation December 31, 1963.

OUTLOOK

Appraising the future of the copper industry on the basis of past and current activities, trends, and future plans, there will be adequate sources of ore, ample processing equipment, and copper should keep at least its share of the metal market. There is a slowly rising trend in world consumption principally because expanding electrification, increased use of copper in the construction industry, and efforts to accelerate progress in developing nations.

Many companies, at home and abroad, are actively exploring and developing new or additional sources and are expanding facilities to meet anticipated future requirements. It has been estimated that mine capacity in the United States will increase at slightly less than 2 percent to 1.6 million tons by 1968. Activities contributing to the increased production are expansion of facilities of The Anaconda Company at Butte, Montana; the Utah Copper Mine and Chino Divisions of the Kennecott Copper Corp.; the San Manuel Copper Corp.; and development of new mines by The Anaconda Company near Tucson, Ariz.; Calumet and Hecla, Inc., on the Upper Peninsula of Michigan; Duval Corp., near Kingman, Ariz.; and the United States Smelting, Refining and Mining Co., near Bayard, N. Mex. Kennecott Copper Corp. is intensively exploring a deposit in Alaska. Development of a mine in Maine will return New England to a copper-producing area, a position it held from colonial times until recently. World mine capacity will be increased an additional 400,000 tons by expansion of facilities at a number of mines in Canada and development of new ones, particularly in Ontario and British Columbia; expansion and developments in Chile; expansion of facilities at producing mines and the development of the Chambishi mine in Northern Rhodesia; development of the Palabora mine in the Republic of South Africa; and more modest expansions in Australia and the Philippines.

Consumption of copper in the United States has lagged behind the expansion of the national economy as measured by such indicators as the gross national product and the increase of population.

Reasons for the slower rate of growth of the copper industry are twofold, replacement in use by aluminum and to a certain extent by other materials in electrical power transmission and building construction, and less raw materials and more services are required to fulfill the needs of the complex society of modern America. Thus copper competes with other raw materials and vies with communications, education, medical care, recreation, transportation, and other services for its share of the money of the American consumers. For these reasons the

consumption in the United States is expected to increase at slightly less than half the rate of the increase of the gross national product. Based on historical averages the growth of the consumption of copper will be approximately 1.5 percent a year—a rate slightly less than that anticipated for the growth of population.

Rising standards of living and increasing populations in developing nations indicate that the growth of consumption of copper in the world in the next decade will approximate twice that of the United States. This projection is predicated on the assumption that adequate copper will be available at prices as competitive with aluminum and other substitute material as at present.

Imports of copper in ore, concentrate, and smelter products have been fairly constant and have averaged slightly less than 400,000 tons for the past 10 years. However, the imports may diminish in proportion to an increase in competitive buying by foreign interests and the rate by which currently planned new refineries in foreign countries are constructed.

Strong national strivings in South America and the emergence of new, unstable nations in Africa will continue to affect adversely the place of copper in international trade. Internal political and economic pressures will tend to maximize mine production of copper and cause construction of facilities that will affect smelting and to a greater extent refining in the United States. Since these developments will not be made by economic considerations, world production will tend to increase in a nonuniform manner disturbing trade patterns and sustaining an imbalance between supply and consumption.

Smelter capacity in the United States may increase in areas where mine production increases, but may decline where dependent on imports for feed. There is little indication that domestic refinery capacity will be expanded, in fact some refineries may experience difficulty in obtaining raw material.

Secondary copper recovery will vary roughly with the business cycle. Most of the fluctuation will be in the quantity of copper recovered from new scrap, which will range from 450,000 to 550,000 tons a year. Study of the past pattern of production from old scrap and consideration of limited generation of the material indicates that old scrap will contribute a fairly stable supply of about 450,000 tons of secondary copper annually.

PROBLEMS

The copper industry is confronted with technical and economic problems related to resources, mining, concentration, reduction, fabrication, uses, and prices.

A fundamental problem of the domestic industry is the assurance of a continuing supply which entails finding and developing new resources. Exploration is frequently so uncertain and so costly to pursue that it is considered excessively expensive by many. However, maintaining an adequate domestic supply is essential to offset drains of an expanding economy or interruption of foreign supply by adverse events. Worldwide aspects of the supply problem relate to political and social instability in some major copper producing areas; and the general geographic separation of the producing and consuming areas of the world.

A major problem of domestic mine production is related to rising costs and depletion of higher grade ore. In nearly all the available ores, the copper and byproduct minerals occur in a very small proportion of the mass of rock that must be mined and processed to recover them. Bulk handling of such low-yield materials is economic only under rigorously planned and supervised operations. Reliable determination of the size, configuration, mineral content, and rock properties of an ore body is a necessary and costly prerequisite. Preparing an ore body for mining by open-pit or caving methods requires a large initial expense in both money and time. As the depth of underground mining increases, hazards and costs multiply. In open-pit mining the ratio of waste removal to ore extraction increases geometrically with depth.

Concentration, like mining, has problems of efficiently handling bulk materials. Changes in character of mineralization require adjustments of concentration practices and may affect reduction capacities. Reduction is cumbersome, costly, and energy consuming. The affinity of copper for oxygen is such that each melting or casting step is attended by contamination by oxygen unless air is excluded from all molten faces.

The increasing importance of copper recovered from oxide ores by leaching or the segregation process illustrates a problem of material handling in metallurgy. Cement copper from leach solutions and flotation copper from the segregation process are of substantially higher grade than the sulfide concentrates. However, cement copper frequently is fed into the reverberatory furnace with the concentrate and flux to form matte of much lower copper content.

The lack of knowledge of the properties of high-purity copper and the alloys of copper with rare earth elements and rare metals impedes the search for new uses of copper. Incomplete thermodynamic data on the metal and its compounds limit development of new processes and uses.

Closely related to the problems of primary copper production are those of the essential secondary copper industry. Other problems include more widespread and effective methods of scrap collection; greater recovery of metals from scrap and waste material; and less costly methods of identifying, separating, and treating scrap.

One of the most challenging problems of the copper industry is preventing the loss of markets to aluminum, steel, plastic, and other materials and at the same time gain a proportionate share of an expanding market. Additional problems are unexpected price fluctuations, difficulty in predicting supply and demand patterns on which effective planning can be based, and competition between domestic and foreign segments of the industry.

CORUNDUM AND EMERY

By Paul M. Ambrose [1]

CORUNDUM ore is mined mainly from shallow open-cut workings seldom exceeding 20 feet in depth. Screens and jigs, frequently operated by hand and supplemented by handpicking, are used when water is available; otherwise the ore is entirely handpicked. Emery is mined exclusively from open pits.

In 1963 about 2,000 short tons of abrasive-grade natural corundum mostly from Southern Rhodesia was imported into the United States and processed by one firm for sale principally to the optical industry. There was no domestic production.

About 7,000 short tons of emery is mined by two firms near Peekskill, N.Y., and 1,000 tons a year is imported from Greece and Turkey by two firms in Massachusetts. Virtually all the imported and a small portion of the domestic emery is used in abrasive paper and cloth and as a polishing grain; the remainder is used as a nonskid element in pavements and stairways.

Artificial abrasives, because they are harder and more uniform, have largely replaced corundum and, to a lesser extent, emery.

World reserves of corundum and emery are large in comparison to consumption. Domestic and Canadian occurrences of corundum are not presently commercial, and the domestic reserve of emery is small.

Demand for corundum is expected to continue as long as a sufficient supply is available at competitive prices. The demand for emery for abrasive application is expected to decline 300 tons to 500 tons per year; however, use of emery for nonskid flooring is expected to increase slightly.

Problems of the corundum and emery industries are related to the lack of definitive methods of comparing their abrasive properties with those of other materials. The dependence of the United States on foreign overseas sources of corundum may create problems of supply in wartime, and the lack of low-cost supplies of emery near major industrial areas other than New York may lead to substitution in some localities.

BACKGROUND

This chapter deals only with abrasive corundum and emery. Gem corundum, principally sapphire and ruby, is included in the "Gem Stones" chapter.

The development of the bonded grinding wheel during the 1860's created a demand for high-quality abrasives. To meet that demand, commercial corundum mining in the United States began at Corundum Hill, N.C., in 1871. Other major mines producing corundum were at Buck Creek, Clay County, and near Sapphire, Jackson County, N.C.; Laurel Creek, Raburn County, Ga.; and in Gallatin and Madison Counties, Mont. All have been inactive since 1906, except for short periods during World Wars I and II (*12*).[2]

The introduction of aluminum oxide (synthetic corundum) about 1900 reduced the importance of natural corundum and emery as abrasives in grinding wheels, abrasive cloth, and for polishing grain.

The abrasive qualities of emery from the Greek island of Naxos were known 2,000 years ago. Naxos and adjacent islands continue to produce an emery much favored in Europe for grinding wheels. About 100 years ago, emery from Turkey first entered the world market.

Emery mining in the United States began near Chester, Mass., in 1868; near Peekskill, N.Y., in 1883; and near Whittles, Va., in 1917. Emery is produced in New York by DeLuca Emery Mines and Di-Rubbo & Ellis from deposits near Peekskill, N.Y. In 1963 these firms produced about 6,732 tons, valued at $119,000. The Massachusetts mines closed in 1912, and the Virginia mines closed in 1923.

[1] Commodity specialist.
[2] Italicized numbers in parentheses refer to items in the list of references at the end of this chapter.

SIZE, ORGANIZATION, AND GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

Abrasive-grade corundum from the Republic of South Africa and Southern Rhodesia is imported and processed by the American Abrasive Co. of Westfield, Mass. In 1963, 2,035 short tons of abrasive-grade corundum, valued at $51,334, was imported. The finished products are sold directly to the optical and grinding wheel industries.

Corundum also is produced in India, Malaysia, Nyasaland, and Mozambique. At one time the United States, Canada, and the Malagasy Republic were substantial producers. The U.S.S.R. has extensive deposits in the Ural Mountains and in Central Siberia, but its output does not enter foreign trade, and production data are lacking (*2*, *4*, *6*).

Emery is imported from Greece and Turkey by Washington Mills Abrasive Co., North Grafton, Mass., and by Hamilton Emery & Corundum Co., Chester, Mass. There were 10 manufacturers of emery paper and cloth in 6 States and 33 manufacturers of bonded emery abrasives in 11 States. In 1963 these firms produced 74,018 reams of emery paper and cloth, valued at $2,670,165. This was about 3 percent of the coated abrasives, including quartzite, garnet, aluminum oxide, and silicon carbide sold that year.

DEFINITION OF TERMS, GRADES, AND SPECIFICATIONS

Corundum is a natural anhydrous aluminum oxide. In its purest form it includes various gem stones, such as ruby (red) and sapphire (blue, yellow, green, purple, and white). Emery is a mixture of corundum, magnetite, and other minerals. It contains from 55 to 75 percent aluminum oxide, commonly in the form of fine crystals of corundum. Three commercial types of emery are recognized in the United States—Greek, Turkish, and American. The American type, from Peekskill, N.Y., is spinel emery, a mixture of spinel, corundum, and magnetite. The abrasive efficiency of each is normally determined by the percentage of included alumina.

Typical partial analyses of emery types are as follows:

Type	Alumina (percent)	Silica (percent)	Magnetic iron oxide (percent)
Turkish	62	2	33
Greek	63	5	29
American	55	7	30

National Stockpile Specification P–18–R, of November 28, 1961, covers two grades of corundum ore.

TECHNOLOGY

Significant Properties

On Mohs' scale the hardness of corundum is 9. The artificial abrasives—aluminum oxide and silicon carbide—have a Mohs' scale hardness slightly above 9 and emery has a rating of 8 to 8.5. The specific gravity of both corundum and emery is about 4. On the Wooddell and Knoop scales of comparative hardness, based on actual working conditions (*13*), the artificial abrasives are rated considerably harder than corundum. Because they are harder and of more uniform quality, artificial abrasives have displaced corundum, and to a lesser extent emery, in industry, except for a few special operations.

Corundum suitable for abrasive purposes has a prominent basal cleavage that causes the crystals to break readily with smooth flat surfaces at right angles to the axis of elongation through successive reductions in size. In this respect it differs from aluminum oxide, which has a conchoidal fracture. The difference in type of fracture may explain why corundum seems to be particularly suited for certain kinds of grinding.

Geology

Corundum occurs as a constituent of various igneous and some metamorphic rocks, including serpentine, mica schist, quartz schist, and crystalline limestone, and in contact metamorphic zones. Corundum also occurs in alluvial deposits.

In Africa corundum usually occurs in one of three forms: (a) Crystal corundum, comprising loose or isolated crystals derived from pegmatitic intrusions in decomposed or partly decomposed country rocks, generally basic in character; (b) boulder corundum, or detached rounded masses of corundum-bearing rock that have resisted disintegration. The boulders are usually composed of interlocking crystals of corundum, with lesser amounts of feldspar, mica, and other associated minerals filling the interstices; and (c) reef corundum, lenticular masses of rock locally called "plumasite," composed largely of corundum and a white acid-type plagioclase feldspar (*6*).

Emery deposits are products of contact or regional metamorphism. On the island of Naxos, which is principally made up of gneisses and mica schists, alternating with crystalline limestone, masses of emery from 15 to 50

feet wide and up to 300 feet long are closely associated with the limestone (*2*).

In Turkey, the deposits occur as pockets or masses in limestone, and range from a few feet to 200 feet in width and up to 300 feet in length. Emery occurs also as detritus resulting from the weathering of the rocks, and in a compact red clay which occurs in shallow depressions in the limestone (*2*).

Near Peekskill, Weschester County, N.Y., emery deposits occur on the border of an igneous complex composed of hornblende and olivine pyroxenite. The ore is a black or gray, massive, hard, fine-granular spinel emery (*3*).

Mining and Milling

In general, corundum is mined from shallow open-cut workings which seldom go deeper than 20 feet. In past years, some workings reached a depth of 100 feet. Few of the operations are mechanized (*7*). In the residual deposits crystal corundum is generally clean and free from adhering impurities, and the problem of recovery is to separate the crystals from the accompanying waste. Usually the ore is screened to minus 1- plus ⅛-inch, and washed in a rotary pan similar to that used for the recovery of diamonds, or in small jigs, often operated by hand. The larger crystals and fragments can usually be recognized during the screening and are picked out by hand. If water is not available for washing, the material is hand-picked. No effort is made to recover the minus ⅛-inch material (*11*). The massive corundum deposits in Southern Rhodesia are mined by open-pit methods, and the ore is handpicked and shipped in bulk.

All producing emery mines in the United States, Greece, and Turkey are open pits.

USES

Corundum and emery are used as abrasive components of grinding wheels and abrasive cloth or for polishing grain. Their use has been virtually supplanted by artificial abrasives, and less than 4 percent of the abrasive material now used is corundum or emery.

Corundum is used in the rough and finish grinding of optical glass. For rough optical grinding, corundum grain from 60- to 275-mesh is employed. As the corundum grain breaks down it is collected with the powdered glass it has abraded. This material is treated by water classification to produce superfine corundum for finish grinding of optical glass (*8*). A grade of corundum not suitable for abrasive purposes is used locally in Southern Rhodesia for refractories.

Turkish emery is preferred by industry over other types for abrasive paper and cloth and in recent years the combined sales of emery paper and cloth have been about 3 percent of the total coated abrasives sold. Emery is also used in lapping and polishing compounds, and for polishing grain. During the last decade, domestic emery has been used as a nonskid element in pavements and stairways, and this is now its largest use. The low price of domestic emery in comparison with other abrasives is a factor in expanding this use (*5*).

ALTERNATE MATERIALS

Aluminum oxide, made principally from abrasive-grade bauxite, and partly from Bayer process alumina, has largely replaced corundum and emery in grinding and polishing operations. Some garnet is used in optical lens grinding. Corundum and emery still are used in a few applications either because of price, performance, or preference. Examples are the use of corundum for lens grinding and emery for metal polishing. To a lesser extent, silicon carbide has also become competitive as the abrasive element in grinding compounds.

Among the natural abrasives, diamond, because of its extreme hardness, and garnet, because of its unique fracture, also have replaced corundum and emery for some uses.

Corundum and emery formerly were used for sandblasting and sandpaper to a limited extent, but have been replaced almost entirely in these uses by lower priced sand and quartzite.

RESERVES

The Republic of South Africa, Southern Rhodesia, and India have corundum deposits occurring over large areas. No reserve data are available, but it seems probable that the present corundum output can be maintained for the foreseeable future. Nyasaland, Mozambique, and Malagasy Republic have substantial deposits, and corundum is known to occur in several other countries, including Brazil and Malaysia. There is no reserve of corundum in the United States or in Canada. The U.S.S.R. may have the largest reserve of corundum in the world in the Ural Mountains and in Central Siberia.

A study of the emery deposits near Peekskill, N.Y., made by the Bureau of Mines in 1955, indicated a reserve of some 60,000 tons of emery. The potential resource is many times the indicated reserve. The emery deposits near Chester, Mass., have not been worked since 1913, and those in Virginia for over 30 years. Emery occurrences are known in Pennsylvania and

780-887 O—65——20

North Carolina. No estimates of the ore reserves at these locations are available.

Greek and Turkish emery deposits have reserves reported as "large," and it seems probable that their present output can continue for many years. With mechanization, and possibly beneficiation, these areas can probably increase their emery output, lower costs, and improve the product. Emery from U.S.S.R. deposits does not enter free world trade. The total reserve is reported to be large. Canada has no known commercial deposits. Minor reserves are known in Bavaria.

SOURCES OF STATISTICAL INFORMATION

The Bureau of Mines annually compiles data on the world corundum production and canvasses the domestic emery producers. The Department of State reports information on the production of emery in Greece and Turkey.

PRODUCTION, CONSUMPTION, AND TRADE

The world production of corundum and emery, by countries, is shown in tables 1 and 2; imports into the United States are shown in tables 3 and 4. It is estimated that more than one-half of the emery consumption in the United States is used for nonskid floors and pavements.

There is no duty on corundum ore and concentrate. The import duty on graded corundum is one-half cent a pound. There is no duty on emery.

TABLE 1.—*World production of corundum by countries* [1] [2]

[Short tons]

Country [1]	1954–58 (average)	1959	1960	1961	1962	1963

STRATEGIC CONSIDERATIONS AND GOVERNMENT PROGRAMS

The Western Hemisphere has no commercial corundum deposits, but artificial abrasives can replace corundum for all uses, although at a higher cost and some undetermined loss in efficiency in certain operations.

The emery resources near Peekskill, N.Y., probably are adequate for many years, and the product is acceptable for the domestic market both in quality and price. Only a few consumers feel that they must have imported emery, and in time of shortage, artificial abrasives can probably be substituted for emery without much loss of efficiency.

Consumers of corundum and emery are concentrated in the northeastern section of the United States (*9*).

Corundum is included in the list of strategic and critical materials for stockpiling, principally because of its use in lens grinding. On June 30, 1964, government inventories totaled 2,008 tons of corundum ore, all of which was in the national (strategic) stockpile. The maximum objective was 2,500 short dry tons.

PRICES

Water classified corundum optical powders ranged from $0.34 to $1.12 per pound according to the fineness of the product. The availability of finer powders between 1959 and 1963 was largely responsible for the increase from $0.63 per pound for the finest size in 1959 to $1.12 for the finest size in 1963.

Emery from Turkey and Greece was quoted at 11 to 14 cents a pound, depending on particle size, compared with 8 cents a pound for equivalent domestic emery in 350 pound bags. Domestic emery aggregate for use in nonskid floorings was quoted at 8 to 11 cents a pound for graded sizes in quantities of 25 short tons, packed in 100-pound paper bags.

TAXES

There are no special taxes on the corundum or emery industries. Producers of corundum are granted a depletion allowance of 23 percent on domestic and 15 percent on foreign production. Producers of emery are granted a depletion allowance of 15 percent on both domestic and foreign production.

TRANSPORTATION

Transportation costs on corundum from the African mines to Westfield, Mass., total about $35 a short ton. Ocean freight from Turkish or Greek ports to New York or Boston on emery ore ranges from $10.00 to $12.50 a metric ton.

RESEARCH

Practical techniques for evaluating natural corundum have been developed by the National Bureau of Standards (*1*). Private industry has made some studies on the use of emery for nonskid pavements and airport runways. Since 1952 the Federal Bureau of Mines has conducted continuing research on techniques for production, fabrication, and testing of numerous metallic borides, carbides, nitrides, and silicides. Some of these compounds may develop into suitable replacements for corundum and emery.

OUTLOOK

For certain specialized abrasive uses, corundum probably will continue to be in demand as long as a sufficient supply is available at comparable prices.

Consumption of corundum in the United States is expected to remain fairly constant at the rate of about 2,500 tons per year for several years. Its use in optical grinding should increase slightly, while other uses decline because of competition from manufactured abrasives, particularly aluminum oxide.

The use of emery in abrasive products, which has declined at an average rate of over 500 tons per year for the past 10 years, is expected to continue to decline, but at a lower rate. Emery for nonabrasive applications, principally nonskid concrete surfacing, should remain fairly constant with possibly a slight upward trend because of use in nonskid paving.

Resources of foreign corundum and emery, and domestic emery are believed to be adequate for the forseeable future although quantitative data are not available.

Competition from other abrasive materials, particularly artificial abrasives and industrial diamond, will be keen due to continuing product improvements, standardization of quality, and utilization research conducted by the abrasives manufacturers, processors, and distributors.

PROBLEMS

Corundum and emery share the overall problem of the abrasive industry; namely, a lack of definitive methods of evaluating the comparative abrasive properties of the various minerals and materials. Hardness, per se, does not assure that a material will be a good abrasive. Other factors, including type of fracture, crystal form, friability, and ability to withstand heating also determine abrasive value. Consequently, personal preference and price usually dictate the choice of abrasives.

Lack of adequate data on the relative grinding efficiency of corundum and emery versus the major abrasive products, aluminum oxide, silicon carbide, and diamond, makes it difficult for corundum and emery to compete most effectively in the relatively few areas where they have a real advantage on the basis of cost or product quality.

A major national problem is the lack of known commercial deposits of high-quality corundum in the United States for use in the event foreign supplies become unavailable.

The major problem of mines producing abrasive-grade emery is to maintain production at a profitable level while demand is decreasing because of competition from manufactured abrasives, labor costs are rising, and the ratio of waste rock to ore is increasing.

Domestic sources of emery are remote from major consuming areas other than the Northeastern States. This factor encourages the use of lower cost but less efficient local abrasive materials or more expensive abrasives which have longer service life and lower maintenance requirements to compensate for high transportation costs.

DIAMOND—INDUSTRIAL

By Paul M. Ambrose [1]

THE WORLD is dependent on natural diamond for industrial stones but if required, necessary crushing bort and powder could be manufactured by processes similar to the one developed in 1955. Natural diamond is available mainly from Africa. Manufactured diamond, first available in the United States, now is produced in five other countries.

"Industrial Diamond, A Materials Survey," was prepared by the Bureau of Mines under the sponsorship of the Office of Emergency Planning to provide comprehensive, fundamental information on diamond essential to the national security. This information circular contains pertinent information on occurrence, technology, production, imports, consumption, exports and history usually in some detail and occasionally back to 1900 (*5*).[2]

Substantial demand for industrial diamond began with the development of hard materials, such as tungsten carbide, and the need for an abrasive to grind and polish them. This created an expanding market for industrial diamond material unsuited for gems, which formerly was difficult to sell. World production of industrial diamond reached 30 million carats in 1963, worth about $120 million. The Congo (Leopoldville) was the largest source.

The principal primary source of diamond is believed to be kimberlite, which occurs in the form of pipes, dikes or sills. Placer deposits derived from the erosion of the original diamondiferous rocks are a more important source of industrial diamond material, supplying over 90 percent of the world output.

The largest outlet for industrial diamond is in the manufacture of abrasive grinding wheels. Industrial diamond also is used in grinding wheel truing and dressing tools; in core, oil well, and blasthole drill bits; lathe tools; wire drawing dies; and hardness indenters. In addition, whole diamonds and crushed bort are used in diamond saws, and diamond powder is used to polish metal parts and jewel bearings.

Several cutting or shaping techniques other than grinding have been developed to reduce the use of industrial diamond, some of which have proved competitive. Their application in industry is, to some extent, dependent on the availability and price of industrial diamond.

Manufactured diamond, produced by General Electric Co., has proved a satisfactory abrasive and makes the United States less dependent on African sources of industrial diamond. Manufactured diamond also is produced in Ireland, Japan, the Republic of South Africa, Sweden, and U.S.S.R.

The world reserve of industrial diamond is estimated to be about 600 million carats, of which 99 percent is in Africa.

Research directed toward the improvement of diamond wheel manufacture and operation and the setting of diamonds in core and oil well bits has improved the quality and quantity of work done.

Since 1946 the Bureau of Mines has conducted research on hard materials and abrasives that may be substituted for diamond in certain applications.

Large reserves of natural diamond in Africa, manufactured material, and the salvage of diamond from industrial wastes give the users of industrial diamond an assurance of supply that should greatly encourage its use. With competition entering the supply field, the possibility of lower prices is an added stimulant.

Major problems of the abrasive industry include a lack of low-cost effective substitutes for industrial diamond, the need for definitive methods of evaluating its abrasive qualities, and a lack of data on consumption.

[1] Commodity specialist.
[2] Italicized numbers in parentheses refer to items in the list of references at the end of this chapter.

BACKGROUND

Probably the first industrial use of diamond was in the form of diamond powder for polishing gem diamonds and other precious stones. Diamond from the early discoveries in India, Borneo, and Brazil found little industrial use. As early as 1819 a patent had been issued in England for drawing wire through a diamond die and glass cutting was an important early use for diamond.

The discovery of the South African diamond mines in 1867 filled the market with industrial material and provided an ample supply for diamond drill bits and grinding wheel truing and dressing tools.

Diamond grinding wheels became important during World War I when German inventors introduced cemented-carbine cutting tools. Grinding wheel manufacturers are now the largest users of industrial diamond.

Prior to World War II the supply of industrial diamond far exceeded the demand. Before 1939 nearly 124 million carats of industrial diamond had been mined, 52 million carats had been used by industry, and there was an apparent surplus of 70 million carats. Between 1940 and 1945 the visible supply was reduced 33 million carats and between 1946 and 1960 it was reduced another 42 million carats. Increased use of diamond and stockpiling has resulted in a nearer balance between supply and demand.

SIZE, ORGANIZATION, AND GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

Extensive use of diamond by industry dates only from shortly before World War II (*8, 9, 19*). From 1936 to 1956 imports of industrial diamond into the United States rose from about 1 million carats to 16 million carats valued at nearly $75 million, mainly because of the adoption of cemented-carbide cutting tools by the metal-cutting industry. In 1963 imports were 12 million carats valued at $50 million.

Africa produces about 90 percent of the world supply of natural industrial diamond, U.S.S.R. 9 percent, and South America less than 1 percent. In 1963 the Congo (Leopoldville) produced 66 percent of the total world production; followed by Ghana, 7 percent; Republic of South Africa, 9 percent; and Sierra Leone, 3 percent. Seven other countries account for the rest of the African output.

Most of the world natural diamond sales are made through the Central Selling Organization which is made up of Diamond Corp., Ltd., The Diamond Purchasing and Trading Corp., Ltd., The Diamond Trading Co., Ltd., Industrial Distributors Ltd., and the Diamond Development Co., Ltd. Another organization, Diamond Producers Association, has great enough influence over the combined group to make it possible for minority interests to be heard (*5*, p. 100, 107–112), (*24*).

The industrial diamond product manufacturers in the United States are centered largely in the Northeastern States, with a few firms in the Los Angeles, Calif., area and in the Midwest.

DEFINITION OF TERMS, GRADES, AND SPECIFICATIONS

All diamond material is suitable for industrial use, but some, because of its color, structure, or size, is more valuable for gem purposes. Gem diamond is discussed in the Gem Stones chapter. Industrial diamond is classified usually according to its potential use into *industrial stones*, such as: Die stones (for wire drawing dies); tool stones (for shaped tools, hardness indentors, etc.); dresser stones (for truing grinding wheels and tools); and drilling stones (for core and blasthole drilling, stone saws, etc.); and *bort* (usually fragmented, for use in making grinding wheels, saws, impregnated core drill bits, and diamond powders).

These classifications are subdivided according to quality, size, crystal habit, and color into over 100 groups. Classification and grading of industrial diamond are strongly influenced by the personal factor and require much skill and training (*28*).

The standard carat in use is the "metric carat" weighing 200 milligrams. It was adopted by international agreement in 1913 and was legalized in the Republic of South Africa in 1922. A previously used "Board of Trade" carat weighed 205 milligrams. Using the standard carat, 2,268 carats weigh 1 pound, and 5,000 carats weigh 1 kilogram. A common system of designating the weight of individual stones is the point system, wherein 100 points equals 1 carat. Smaller sizes are usually classified by passing them through screens. Diamond smaller than 60-mesh may be called "sand," "powder," or "dust" based on progressively decreasing size.

Dana, Bauer, and other authorities state that bort (also spelled boart, bortz) is a cryptocrystalline aggregate of diamonds, but the term is often used by the trade to mean any diamond material that is not of gem quality. Also the terms "common goods," "rejections," and "rubbish" are applied to the less desirable diamond material used for industrial purposes.

Machine shop waste containing diamond from grinding operations is called "sludge" if it is obtained from wet-grinding and "swarf" if obtained from dry-grinding.

The Bureau of the Census has adopted the following designations for the various classifications of industrial diamond imported into the United States: Miners diamond; crushing bort; powder or dust; other, not advanced in condition or value; other, advanced in condition or value; and synthetic.

TECHNOLOGY

Geology

Economically minable diamond occurs in kimberlite pipes, dikes, and sills, and in placer deposits. Over 90 percent of the world output of industrial diamond is from placer deposits.

Geological evidence indicates that diamond was formed in the kimberlite. The fact that diamond is not present in the majority of the known kimberlite occurrences throughout the world indicates that the exact conditions requisite for its formation were not present everywhere.

Although the kimberlite pipes in the vicinity of Kimberley, South Africa, showed practically no surface enrichment, other occurrences, such as the Premier mine in the Transvaal and the Williamson mine in Tanganyika, had a marked concentration of diamond near the surface.

Of the 150 kimberlite pipes and dikes discovered so far in South Africa, 16 have been worked for diamond, and only 11 have proved profitable (*33*).

The numerical ratio of profitable to unprofitable or barren occurrences of kimberlite, in any particular area, affords an indication of the likelihood of a new discovery of economic importance. Within a radius of 15 miles of Kimberley, Republic of South Africa, the ratio is one commercial mine to three barren kimberlite pipes. In the Jagersfontein area, Republic of South Africa, the ratio is 1:6 and in the Premier area, 1:10. In the vicinity of the Williamson mine, Tanganyika, the ratio is 1:26. None of the kimberlite occurrences in the Congo (Leopoldville), outside the Bakwanga area, has proved rich enough to work.

Commercial deposits in 1958 included six kimberlite pipe deposits—three near Kimberley, one at Jagersfontein, and one near Pretoria, Republic of South Africa (Premier mine), and one at the Williamson mine in Tanganyika—a kimberlite sill in Congo (Leopoldville), at Bakwanga, and a kimberlite dike in the Republic of South Africa, at Mallin.

The diamond-bearing ore at the Kimberley mine persisted to a depth of at least 3,500 feet, and at that point the yield was somewhat better than at the 2,500-foot level. However, rising mining costs caused the suspension of mining operations. Outside the Kimberley area, commercial values have seldom been found to continue over a large vertical range (*33*).

Diamond placer deposits are derived from the erosion of kimberlite or from the reconcentration of older placers. They range in age from Precambrian to Quaternary.

In South-West Africa and the adjoining areas of Cape Colony diamond is found in old beach lines as much as 100 feet above the present sea level. Diamond is also found in waters off the coast of South-West Africa.

The alluvial deposits now being worked in Sierra Leone, Guinea, Ghana, Congo (Leopoldville), and Angola are of recent age. They occur in stream gravels and bench deposits. Except for a kimberlite sill at the Bakwanga mine in Congo (Leopoldville), the source of diamond has not been found.

In the Lichtenburg diamond field in the Transvaal the diamonds are in the channels of an old river system. The diamonds in South America, Australia, Borneo, and India are in recent stream gravels.

In the United States diamond occurs in minor quantities in the detrital cover of a kimberlite pipe in Pike County, Ark. (*27*). Diamond has been found in glacial drift in Wisconsin, Michigan, Indiana, and Ohio and in placer gold workings in California and Montana. Individual diamonds have been picked up in 10 other States.

In 1956 a Russian geological expedition announced the discovery of diamondiferous kimberlite pipes, culminating a 6-year search for diamonds in Central Siberia. The principal field is in the basin of the Vilyui River in the northwestern part of the Yakutian A.S.S.R. Another field, 400 miles distant, is in the basin of the Daaldyn River. So far, no information indicating the definite extent of these discoveries has been published, but production of diamond by the U.S.S.R. in 1963 was estimated at 3 million carats of which 2.76 million carats was industrial diamond.

Mining and Milling

At the Premier and Jagersfontein mines and the mines at Kimberley the kimberlite pipes are mined underground by caving. The kimberlite, after crushing, is concentrated by heavy medium, followed by jigs, grease belts, and electrostatic separators, sometimes supplemented by handpicking (*13*). The ore contains about 1 part of diamond to 15 million parts of waste.

At the Bakwanga mine in the Congo (Leo-

poldville) the overburden is removed with continuous bucket excavators of German design. Mining of the diamond-bearing material is done with power shovels. The ore is treated by the same methods as that from the pipe mines in the Republic of South Africa. The ratio of ore to waste is about the same as in the pipe mines.

At the Mallin mine in the Transvaal a nearly vertical dike 2½ feet wide and 8,000 feet long is being mined underground by open stoping. The ore is crushed, jigged, and passed over grease tables. The workings have reached a depth of 600 feet. The ratio of ore to waste is not known, but is probably the same as in the pipe mines.

Mining and milling methods at the Williamson mine in Tanganyika and the DeBeers mines in South-West Africa are similar to the operations at the Bakawanga mine (*31*).

At the diamond placer mines in Angola, Congo (Leopoldville), Ghana, and Sierra Leone the overburden is removed by a combination of mechanical excavators and ground sluicing. The gravel is concentrated in diamond pans or jigs at movable washing plants. Concentrate then goes to central clean-up stations for final separation by grease tables, electrostatic separators, or by handpicking (*20*, *29*, *30*, *32*).

Virtually no data are available on the quantity of fine diamond remaining in the tailing from diamond concentrators because no practical method has been devised to measure the diamond content of materials. Thus far, when new concentrating methods have been developed, such as electrostatic separation and flotation, producers have had to determine the feasibility of recovering additional diamond from tailings by plant tests.

Sea mining of diamonds off the coast of South-West Africa started in 1961 in a pilot floating mining plant which was wrecked during a severe storm in June 1963. Its replacement was equipped in less than 3 months. Special anchors are put out in four directions to keep the vessel working under controlled conditions. Solids and salt water are brought up in 20 to 26 inch flexible tubes by compressed air and delivered to a scalping screen that removes coarse material. The water and fines are separated on a second vibrating screen and the diamondiferous fraction is sent to a heavy medium section. A hydrocyclone with a ferrosilicon slurry separates a heavy fraction containing diamonds. Diamond is finally recovered by handpicking.

Few of the South African diamond operations are mechanized. Usually the mining equipment consists of a pick, shovel, and batea.

In some instances crews using diving equipment work the bottoms of the rivers. The pay gravel is scraped from the bedrock, hoisted to surface, and panned to recover the diamond.

USES

The largest use for industrial diamond is in abrasive grinding wheels. Crushed bort and powder in the coarsest grit size commensurate with the finish desired are used.

Better quality rough and uncut and cut and polished stones from ¼ to 4 carats are set in holders and used to dress or true grinding wheels.

The smaller sizes of industrial stones (from 120 per carat to 3 per carat) or crushed bort are used in core, oil well, and blasthole drill bits (*7*).

Good quality cut and polished stones from ¼ to 4 carats are used for lathe tools and tools for thread and gear cutting. These stones are cleaved or shaped to adapt them for their intended use. For wire-drawing dies stones of the best quality in sizes from 20 per carat to 1 carat are required. First-quality stones for hardness indenters range in size from 12 per carat to 3 per carat. Whole diamonds and crushed bort and powder are used in diamond saws. Diamond powder is used to polish hard materials.

BYPRODUCTS AND COPRODUCT RELATIONSHIPS

Gem-quality diamond is a coproduct of industrial diamond at most mines, accounting for over two-thirds of the value and about one-fifth of the quantity. At the Bakwanga mine, however, gems represent only about 2 percent of the quantity and 25 percent of the value of production. In South-West Africa over 90 percent of the quantity produced is of gem quality, representing at least 98 percent of the value. A few diamonds have been recovered from gold dredging in New South Wales.

ALTERNATE MATERIALS AND TECHNIQUES

Since 1945 various substitute processes for machining hard materials and sharpening carbide tools have been developed by industry. For some industrial applications they have been found to be as satisfactory as diamond grinding wheels or tools. These include electrodischarge processes, including electrosparking and electroarcing, electrolytic processes, ultrasonic abrasive grinding, silicon carbide belt grinding, and silicon carbide wheel grinding.

The technical applicability of these substitute methods is shown in table 1. In the drilling of small diameter deep holes, embossing, and tapping, the electrodischarge and the ultrasonic processes can be used where the diamond grinding wheel cannot be used.

TABLE 1.—*Technical applicability of substitute processes*

Machining and grinding operations	Electro-discharge	Electrolytic	Ultrasonic	Silicon carbide belts	Silicon carbide wheels
Cemented carbides	yes	yes	yes	yes	yes
Metals (steel, etc.)	yes	yes	yes	yes	yes
Nonmetals	no	no	yes	yes	yes

Tapping	yes	no	yes	no	no

[1] Data not available.

The Bureau program on borides, carbides, nitrides, and silicides, described under Research, may develop substitutes for industrial diamond in some of its applications.

Boron nitride, synthesized by General Electric Co. and reported under the trade name, Borazon, is said to be as hard as diamond and to be capable of withstanding higher temperatures.

SYNTHETICS

The General Electric Co. announced the synthesis of diamond in 1955, after years of effort by many scientists in many countries. Virtually no data have been released on the raw materials or the process used, except that extremely high temperatures and pressures are employed. Since the announcement, General Electric Co. has been making an industrial diamond product competitive in quality and price with crushing bort from the Congo (Leopoldville). The company has not released production figures, but it is estimated that by 1963 output would be at the rate of about 4 to 5 million carats annually. Substantial quantities of manufactured diamond also were being made by Ultra-High Pressures Ltd. in plants at Springs near Johannesburg, Republic of South Africa, and at Shannon, Ireland. Other production occurred in Japan, Sweden, and U.S.S.R. Quantitative data are not available but it is probable that adequate facilities were being developed by U.S.S.R.

Industry tests of manufactured diamond in grinding wheels and other applications have shown the material is equal, and in some properties superior, to natural bort. Manufactured diamonds are nearly all single crystals, in contrast to the fragments and slivers of broken crystals that comprise much of the natural bort. Thus, the manufactured diamond has more sharp edges and points, which probably increases its abrasive efficiency (*3*, *16*).

The particle size distribution of the General Electric Co's ungraded manufactured diamond is given in table 2. Present research by General Electric Co. is directed toward improving shape of the crystals, and making larger crystals.

TABLE 2.—*Particle size distribution of ungraded manufactured diamond*

Mesh	Percent	Mesh	Percent
+40	0– 5	−170+230	15–22
−40+80	19–34	−230+325	6–10
−80+120	14–23	−325	5–15
−120+170	14–22		

SECONDARY SOURCES AND RECOVERY

The term "diamond salvage" is used to define the recovery of fine diamond fragments and powders that are present in the swarf and sludge from diamond grinding operations, as well as material from diamond-pointed tools, wheel dressers, diamond drill bits, and broken or discarded diamond wire-drawing dies and grinding wheels (*1*, *21*).

Since 1962 the salvage of diamond material from these sources in the United States has been about 2 million carats annually.

RESERVES

Reserves at the Bakwanga mine in the Congo (Leopoldville) have been blocked out by extensive shaft sinking and drilling. The reserve, estimated at 500 million carats in 1960, was believed to constitute 85 percent of the free world reserve of industrial diamond (*5*). Because of reworking of old ground, new information on old deposits, and the probable existence of considerable diamond off the coast of South-West Africa, the free world reserve of industrial diamond is estimated to be 600 million carats. Since the original estimates were conserative, the actual reserve may be much greater than now anticipated.

CONSERVATION PRACTICES

The development of heavy-medium and electrostatic separation methods permitted the

economic recovery of industrial diamond of much smaller particle size and enable the producing companies to rework old dumps. These methods have greatly expanded reserves of industrial diamond.

SOURCES OF STATISTICAL INFORMATION

The Bureau of the Census collects data on the imports, exports, and reexports of industrial diamond on a monthly basis. Data on diamond production are obtained from Department of State dispatches and mining company reports. Many of the data in the table listing the prodution of each field were compiled in collaboration with Dr. George Switzer, Chairman, Department of Mineral Sciences, Smithsonian Institution. The information through 1961 was compared with data published by Antoine Moyar of Brussels, Belgium, a recognized authority (*19*). No canvass is made of industrial diamond consumers.

PRODUCTION, CONSUMPTION, AND TRADE

Table 3 shows the world production of industrial diamond by countries. Imports during 1959–63 averaged 13,637,000 carats valued at $56,036,000; exports and reexports during the same period averaged 3,666,000 carats valued at $18,531,000. Data on consumption are not available.

There is no import duty on industrial diamond except synthetic diamond and diamond advanced in condition or value. There is a 15 percent ad valorum duty on each of these.

TABLE 3.—*Primary industrial diamond production*

(Thousand carats)

	1954–58 (average)	1959	1960	1961	1962	1963

STRATEGIC CONSIDERATIONS

Industrial stones and bort have been designated as strategic and critical materials for stockpiling. At the end of 1963 the United States had the capacity to produce 4 to 5 million carats of manufactured diamond and 2 million carats of salvaged material, annually, more than one-half of its requirements of crushed or under 40-mesh size industrial diamond. The United States will continue to be dependent on foreign sources, principally Africa, for all of its requirements of material larger than 40-mesh until such time as larger size diamonds can be or are synthetically produced. Stockpile commitments for industrial stones have been met and comprise an emergency supply. On June 30, 1964, Government inventories of industrial stones totaled 24.7 million carats, of which 9.3 million was in the national (strategic) stockpile and 15.4 million in the supplemental stockpile. Stocks of crush-

ing bort totaled 36.6 million, of which 31.1 million was in the national (strategic) stockpile and 5.5 million in the supplemental stockpile.

Although 98 percent of the natural diamond requirements of the free world come from Africa, the total weight of the annual production is only between 4 and 5 tons, so the entire quantity could be dispatched to the United States by air, provided the African supply remains available.

The industrial diamond product manufacturing is distributed through the Northeast States, with its principal concentration in the New York, N.Y., and Newark, N.J., area. There are a few firms in the Midwest and in the Los Angeles, Calif., area.

PRICES

Crushing bort comprises the largest fraction of industrial diamond, sales, and its price is indicative of the price trends of other types. Prices of crushing bort in New York are the London quotations shown in table 4 plus transportation, insurance (all types), and broker commissions.

TABLE 4.—*Average value of industrial diamond imported for consumption into the United States, and the published price of crushing bort in London, per carat*

Year	Value of imports, industrial diamond	London price of crushing bort
1954–58 (average)	$4.11	$2.44
1959	4.78	2.80
1960	3.94	2.80
1961	4.82	2.80
1962	4.16	2.80
1963	4.20	2.80

On June 2, 1958, the General Electric Co. reduced its prices on ungraded manufactured diamond 15 percent to 24 percent, depending on quantity, from the prices quoted on January 1, 1958, as given in table 5; prices for graded diamond in effect December 31, 1963, are also given. Prices of ungraded fines and micron sizes were available on application.

TABLE 5.—*Prices per carat of manufactured diamond*

Quantity (carats)	Jan. 1, 1958	June 2, 1958	Dec. 1963
500	$4.14	$3.15	$2.85
1,000	3.91	3.10	2.85
2,500		3.05	2.80
10,000	3.48	2.96	2.74

RESEARCH

Continued research on diamond synthesis is being conducted by General Electric Co. in the United States and by others abroad to increase the size of the diamond, control the crystal size distribution, improve control of crystal shape, and to lower manufacturing costs.

Industrial Distributors maintains the Diamond Research Laboratory at Johannesburg, Republic of South Africa, devoted to basic and applied research on industrial diamond. The aims of the research center are to promote and extend the industrial uses of diamond, and to improve and promote methods of its recovery and conservation. The services of the laboratory are available to any user or producer of diamond. This is the only laboratory in the world devoted solely to diamond research. A branch of this laboratory was established in Canada in 1959.

Since 1946, the Bureau of Mines has conducted continuing research on techniques for production, fabrication, and testing of numerous metallic borides, carbides, nitrides, and silicides. Some of these compounds may develop into suitable diamond substitutes.

Research is being conducted by industry to improve performance of diamond grinding wheels, through the use of superior bonds, new methods for inserting grains, new operating techniques, and the more extensive and intelligent application of coolants (*6, 25, 26*).

Improvements in diamond drills and in drilling techniques brought about by research have contributed to growth in this phase of the diamond industry (*14, 15, 23*).

OUTLOOK

The importance of sources of industrial diamond will likely be unchanged in the near future. Africa will remain the greatest source of natural industrial diamond. Manufactured diamond will constitute the second largest source, and the quantity of recovered diamond bort will increase.

Continued research, in the United States and abroad, will result in further improvements in the manufacture of diamond which should permit lower costs and even better quality control of the finished product. The upper limits of particle size of manufactured grit has increased and is expected to increase above the 20-mesh size that can now be made. The probability of manufacturing larger material cannot be fully appraised, but significant progress is being made.

Research on borides, carbides, nitrides, and silicides may result in developing compounds

competitive with diamond in some applications. Some properties of synthetic compounds may be superior to those of diamond.

Domestic consumption of industrial diamond has been the fastest growing segment of the abrasive industry and has increased at a rate greatly exceeding gross national product in constant dollars. With an improved supply and price outlook, the continuing trend toward increased automation in grinding operations, superior abrasive properties of diamond, expanded use of diamond abrasives for old applications and the development of new uses is expected to contribute to the increase in U.S. consumption of diamond for the next several years. Continued developments in the control of size and shape of manufactured diamond may result in the increased use of this material but not a replacement of substitute methods for grinding cemented carbides and other hard materials developed when industrial diamond was in tight supply. Industry will continue to increase the efficiency of grinding wheels and diamond tools through research.

PROBLEMS

The diamond industry shares the major problems of the abrasive industry, which include a lack of low-cost effective substitutes for industrial diamond, lack of knowledge on forming large diamond crystals, and a lack of definitive methods of evaluating the comparative abrasive properties of the various minerals and materials. Hardness, per se, does not assure that a material will be a good abrasive (*12*). Other factors, including type of fracture, crystal form, friability, and ability to withstand temperature changes also determine abrasive value.

A continuing problem confronting diamond producers is how to evaluate the efficiency of diamond recovery processes because of a lack of practical methods to measure diamond content of ores and residues.

Other problems are the lack of domestic deposits of natural diamond and the lack of data on the consumption of industrial diamond by grades and uses, which would be of invaluable assistance to industry and in mobilization planning.

DIATOMITE

By Benjamin Petkof [1]

MICROSCOPIC water plants called diatoms secreted silica from the prehistoric seas in which they lived. Upon their death their silicified remains settled to the bottom and formed sedimentary deposits of amorphous silica of great depth. This material, referred to as diatomite, possesses certain physical properties which make it valuable as a filter medium, as industrial filler, for thermal and accoustical insulation, and for many other purposes.

The United States leads the world in production, with primary production in California. Production during 1960–62 averaged more than 482,000 short tons per year, valued at about $24 million.

The principal problems confronting the industry concern the search for new uses, development of specialized processes and equipment for improvement of efficiency and product quality, health hazards, high transportation cost, and need for markets for low-quality diatomite and any coproducts developed during mining.

BACKGROUND

In A.D. 532, the Roman Emperor Justinian I used diatomite brick to lighten construction of a dome 107 feet in diameter in the church of St. Sophia in Constantinople. The first large-scale application of diatomite was as an absorbent for liquid nitroglycerine, developed by Alfred Nobel in 1886; this use is now obsolete. The first extensive use to survive was for filtration of raw cane sugar liquor. This application dates from 1876, when diatomite began to replace paper pulp, compressed cotton, and asbestos-cellulose filter pads (*2*, *6*).[2]

The most important developed domestic deposits were discovered about 1890 near Lompoc, Calif. Insulating brick cut from naturally consolidated diatomite was the first quantity product of the Lompoc mines. In 1906, the first mill was built at Lompoc to pulverize the diatomite. In 1912, new owners of the Lompoc quarries organized the Kieselguhr Co. of America and began a program to develop diatomite as a filter aid. Subsequently, the firm name was changed to Celite Co. This organization acquired extensive adjoining acreage in 1926, and 2 years later was sold to the Johns-Manville Corp. Great Lakes Carbon Corp. has since acquired and developed a large acreage in the Lompoc area (*11*).

SIZE AND GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

The United States is the largest world producer and user of diatomite. During 1963, 15 plants operated by 13 companies produced diatomite. In 1962, 12 companies operated 14 plants, producing an average of 482,000 short tons per year valued at about $24 million. California produced the bulk of domestic supply with smaller quantities from Nevada and Washington. Arizona, Maryland, and Oregon provided minor quantities.

The major producers during 1963 were Johns-Manville Corp. at Lompoc, Calif.; Great Lakes Carbon Corp., at Lompoc, Calif., and Basalt, Nev.; The Eagle-Picher Co. at Colado and Clarke Station, Nev.; and the Airox Co. at Santa Maria, Calif. The remaining nine producers, in Arizona, California, Maryland, Nevada, Oregon, and Washington, furnished about 7 percent of the total production.

Diatomite is mined in the U.S.S.R., Denmark, France, West Germany, Italy, the United Kingdom, and other countries.

[1] Commodity specialist.
[2] Italicized numbers in parentheses refer to items in the list of references at the end of this chapter.

DEFINITION OF TERMS, GRADES, AND SPECIFICATIONS *(4, 8—10)*

The terms "diatomite", "diatomaceous earth", and "kieselguhr" are synonymous and currently preferred for this commodity. Erroneous nomenclature occasionally encountered includes infusorial earth, infusorial silica, tripolite, and other local designations.

Diatomite is largely a fossil accumulation of diatoms, usually with some radiolaria and smaller amounts of foraminifera. These are all microfossils, diatoms being planktonic siliceous plant organisms, while radiolaria are planktonic siliceous, single-cell animal organisms. Foraminifera are calcareous animal organisms. Diatomite is essentially amorphous, hydrated, or opaline silica with various contaminants, such as silica sand, clay minerals, iron, alkalies, and alkaline earths. The chemically combined water ranges from 3½ to 8½ percent. Apparent density of dry consolidated material varies from 20 to 40 pounds per cubic foot, and the dry powder from 5 to 16 pounds per cubic foot.

Unprocessed diatomite has a hardness between 4 and 6½ on Mohs' scale. It is softer than opal, and appears to be only slightly harder than brass, which is considered 3½ on Mohs' scale.

Qualities responsible for the wide use of diatomite include its structure, porosity, low apparent density, strength, elasticity, chemical inertness, low thermal conductivity, light color, high melting point, and large surface area per unit of weight.

Three general grades of prepared diatomite are based on heat treatment after the usual drying and reduction stages. These grades are called "natural," "calcined" or "pink," and "flux calcined" or "white." The natural is that material sold without heat treatment after drying, delumping, and air classification. The calcined grade is similarly processed and is heat-treated in direct-fired rotary kilns using gas or fuel oil without fluxes, while flux-calcined material is calcined with the addition of a fusible alkali salt.

The Great Lakes Carbon Corp. markets its processed diatomite under the trade name of Dicalite, Eagle-Picher Co. Celatom, and Johns-Manville as Celite. The various processed grades are also named or numbered by each company for designating material with certain standardized qualities, such as color, brightness, particle size range and distribution, chemical analyses, and filtering speed.

TABLE 1.—*Typical chemical analyses of processed diatomite (dry basis)*

	Natural (percent)	Calcined (percent)	White (percent)
SiO_2	86.8	91.0	87.9
Al_2O_3	4.1	4.6	5.9
Fe_2O_3	1.6	1.9	1.1
CaO	1.7	1.4	1.1
MgO	.4	.4	.3
Ignition loss	4.6	.3	.1
Undetermined	.8	.4	3.6

TECHNOLOGY

Geology *(2, 4, 6, 11)*

The principal commercially developed diatomite deposits were formed in the late Miocene to early Pliocene ages when volcanic activity furnished silica-rich waters combined with ideal sunlight conditions and plant food supply. Each diatom extracted silica from the waters, secreting it to form minute, siliceous, two-halved envelopes or frustules with various intricate and often symmetrical designs. The two halves are not hinged but fit together. A small diatom measures less than 10 microns, a large diatom 100 microns or more.

The fossil species involved are single-celled algae. More than 12,000 different frustule patterns have been identified. These are microporous structures, many containing substructures only visible under the electron microscope. Although fossil frustules are known to be more than 25 million years old, these shells are identical to those of their living descendants.

Some diatomite beds are of fresh water origin, while others accumulated in ocean waters. Both lake and marine varieties are mined commercially; the frustule patterns of the diatoms from the two sources differ considerably so that the sources of each can be determined with a microscope.

The porous structure of individual diatoms and their massed arrangement impart unusual filtering properties to diatomite. When used as a coating on filter cloth diatomite strains out microbes and colloids from liquids and still permits relatively rapid flow of the filtrate. The filter coating is about 90 percent voids.

Some authorities believe that the marine diatoms of the Pacific Coast propagated in the colder climates of the north Pacific during the Miocene and were carried south by ocean currents and trapped in protected coves of the California coast.

As zones of varying hardness are found in many deposits, particularly near the surface, sampling must be conducted to depth.

Mining (2, 5–6, 9, 11)

All current mining is by open pit. The first step is to remove the overburden with high-speed, power-driven scraper-carriers or bulldozers. Thickness of overburden ranges from 1 to 15 times the thickness of recoverable and usable diatomite. After exposing the diatomite, the mining is done either with the same carryalls used for stripping overburden or with power shovels, loading into trucks. The Johns-Manville Corp. hauls the crude to a series of glory-hole storage shafts at strategic points in the deposit and above a tunnel system. These tunnels terminate near central storage bins close to the mill where crudes of differing grades can be segregated for specification blending.

Mining is complicated by faulting, combined with interbedding of contaminated material which must be wasted. In the Lompoc, Calif., area, selective mining is done within a total vertical thickness of about 1,000 feet. The purest material lies in a series of beds stratified with thin layers of volcanic ash down to the 500-foot level. Stratification lines are seldom more than one-fourth inch thick. Below this zone is a conchoidally fracturing bed several hundred feet thick contaminated with argillaceous material up to 10 percent alumina. Under these two beds may be another series of varying purity, also interstratified with argillaceous diatomite and volcanic ash.

In some cases wet ore goes to a storage area at the quarry where air drying takes place. It is loaded into bottom-dump trailer trucks by bulldozer or slusher hoist and slackline cable drag-scraper for transporting to the mill.

Milling (2, 5–6, 9, 11)

The cost of a plant to process 50,000 tons of diatomite per year is about $2.8 million. Because of the climate, Western plants are of the outdoor type and house only the packing and storage departments and operating control room.

The process outlined diagrammatically in figure 1 covers the Great Lakes Carbon Corp. plant at Lompoc, Calif., which is typical of large-scale diatomite processing.

Diatomite freshly mined from the Lompoc area frequently carries 50-percent moisture by weight; in which case 1 ton of water must be evaporated for each ton of dry diatomite produced—an expensive step in the processing. Drying is accomplished in a hot pneumatic system embodying flash-drying, combination blower-hammer mill comminution, air cyclones, and dust collectors. The diatomite is transported through the system by moving hot gases.

The processing system has three general divisions—a wet-end circut, a calcining section, and a finishing circuit. Crude ore passes through a crusher to a storage bin, discharging to a combination miller-blower with simultaneous injection of a large volume of hot air from a direct-fired oil or gas furnace. The blower injects the ore and hot gases into a system of cyclones and dust collectors, which release air and moisture to the atmosphere, sludge waste to a settling pond, and dry diatomite to the calcining kiln. Impurities not eliminated in the wet-end circuit are usually removed in the finish-end separators.

When flux calcining takes place, 3 to 10 percent by weight of either soda ash, sodium chloride, or caustic soda is added at the crude ore storage bin. Calcination affects the filtering properties of diatomite by changing the surface texture, agglomerating fines, and converting clay minerals which were not removed in the wet-end circuit to aluminum silicate slag. These slag particles are then largely eliminated in the finish-end trapping circuit. Organic matter is removed by combustion during calcination.

Calcination with fusible alkali salts reduces the diatomite surface area per unit volume of the finished product. It also whitens the product, thus increasing its value as a filler where color is significant. Kiln feed temperature is 300° to 400° F; maximum discharge temperature is 2,200° F.

The calcine drops to a hammer mill in which lumps are broken and passes to a milling blower, further reducing the particle size and carrying the calcine to air separators. Any dense particles still in the circuit are trapped in one of these separators and eliminated as a final waste product discharge.

The last air classifier exhausts a fine finished product to a baghouse while discharging a coarser main product. Both of these finished products go to storage hoppers and bagging machines where they are packed in 50-pound paper or cloth bags.

Waste products comprise about 16 percent of total feed.

USES (2, 4–6, 8–10, 12)

The primary industrial application of diatomite is as an industrial filtration medium for liquids ranging from municipal water supplies to alcoholic beverages. Additional uses for diaomite are as fillers, as thermal and accoustic insulation, and for miscellaneous uses such as absorbents, abrasives, polishes, catalyst carriers, glazes, paints, pozzolan, anticaking agent, insecticides, fungicides, fabrication of synthetic silicates, and lightweight aggregate.

780–887 O—65——21

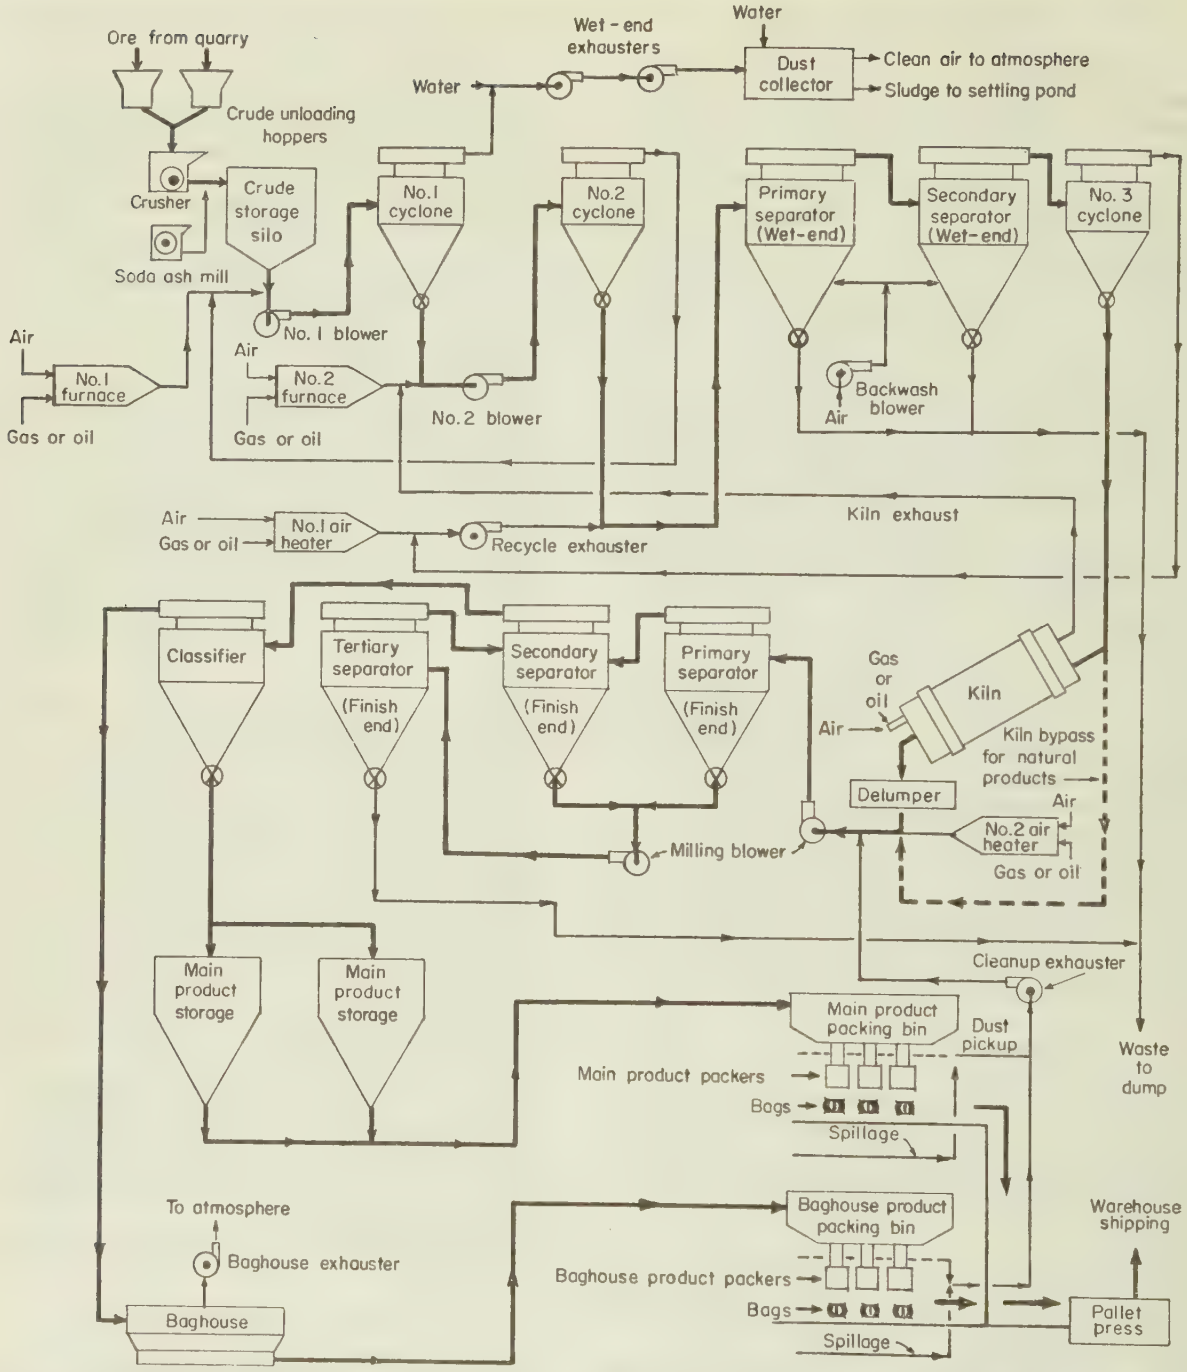

FIGURE 1.—Flowsheet for the Processing of Diatomaceous Earth at Great Lakes Carbon Corp., Lompoc, Calif.

Products filtered with the aid of diatomite include sugar liquor, alcoholic and nonalcoholic beverages, acids, water, petroleum compounds, varnishes, shellac, waxes, greases, resins, plating and dry-cleaning solutions, vegetable oils, gelatins, and antibiotics.

Industrial filters have frameworks supporting filter cloths or wire mesh on which a precoat or cake of porous filter-aid material, usually diatomite, is uniformly deposited. By a difference in pressure between the two sides of this septum, the liquid from the liquid-solids mixture is forced through the filter aid and filter cloth so that the solids to be filtered out are deposited on the precoat.

The continuous filter cycle is started by filling the circuit with a mixture of clear liquid and filter aid until a precoat 1 to 2 inches thick is deposited on the filter cloth. The pulp to be filtered is then introduced with periodic additions of filter aid so that a porous sludge is being constantly deposited on the precoat.

As a mineral filler or extender diatomite is low in cost and imparts such desirable physical properties as light unit weight, strength, elasticity, chemical inertness, low heat conductivity, light color, and reduces reflection of light (flatting agent). Its market as a filler is largely in paint, asphalt, rubber, paper, plastics, and insecticides.

As diatomite is composed of about 90 percent voids and has a relatively high melting point it is a good insulator against heat and sound. It consequently finds applications in furnaces, kilns, refrigerators, safes, and building construction as either brick, shapes, or loose fill.

ALTERNATE MATERIALS

Expanded perlite and silica sand can replace diatomite as a filtration medium. Talc, ground silica sand, barite, gypsum, wollastonite, clay, perlite, vermiculite, chalk, and ground limestone are filler substitutes for diatomite.

Vermiculite, perlite, cinders, expanded clay, shale, and slag can replace diatomite as material usable for lightweight aggregate. When used for insulation, diatomite competes with high-alumina brick, fire clay, asbestos, kyanite, synthetic mullite, mineral wool, expanded vermiculite, and perlite.

RESERVES

Domestic deposits are widely distributed throughout the country. The best known deposits and reserves occur in the West and the largest known reserve, currently being mined, lies near Lompoc, Calif. This deposit extends over many hundreds of acres with beds reaching 1,400 feet in thickness. Arizona, Nevada, Oregon, and Washington currently produce diatomite and have large undetermined reserves of material. The Western States are capable of meeting national requirements for many years. Deposits also occur in nearly all Atlantic coast States from Maine to Florida. However, these deposits have been unable to compete with western material (*4*).

Adequate published information on foreign reserves is not available, but diatomite deposits occur on every continent. Deposits capable of sustaining a processing plant have been confirmed in Iceland. A proved reserve of approximately 6 million tons is available in Kenya, Africa, with an additional 4 million tons estimated to be available. Additional deposits are known in numerous countries with undetermined reserves (*12*).

PRODUCTION, CONSUMPTION, AND TRADE (*12*)

Bureau of Mines statistics are collected on the basis of sales and use of mined diatomite by both producers and consumers. Therefore, the data shown in table 2 are representative of both production and of consumption plus exports.

Government records of imports or exports of diatomite are not available. Presumably very little material is imported because of high transportation costs from most foreign countries. U.S. producers export better quality prepared diatomite, but the quantity is believed to be small.

Crude or processed diatomite may be imported duty free.

World production of diatomite is shown by countries in table 3.

TABLE 2.—*Diatomite sold or used by producers in the United States, 3-year totals*

Years	Quantity, short tons	Average value per ton
1945–47	640, 764	$20. 17
1948–50	722, 670	25. 55
1951–53	908, 448	29. 97
1954–56	1, 105, 279	39. 21
1957–59	1, 349, 340	45. 73
1960–62	1, 446, 625	50. 08

PRICES AND COSTS

Prices vary according to purity of the diatomite, its particle size range, whether it is uncalcined, calcined, or flux calcined, whether it is in bulk or bagged, and the type of bag used.

Average prices of diatomite during 1963 are presented in table 4. These values were obtained from direct canvass of the industry by the Bureau of Mines.

Insulation	49. 91
Abrasive	137. 00
Fillers	50. 07
Miscellaneous	30. 20

TAXES

Producers are accorded a 15-percent depletion allowance in computing Federal income tax on diatomite operations.

TRANSPORTATION

Transportation of diatomite is an important economic factor in the industry. This low-density, high-bulk material must be moved from western production areas in California and

Nevada to the highly industrialized East and Middle West where it is used.

RESEARCH

Several large producers maintain laboratory facilities and engage in research into new uses, improvements, and product standardization. Additional research is carried at the university level, especially in the area of filtration and filter aids. Recent Bureau work has been limited to the investigation of the diatomite-bearing strata of Choctaw and Clark Counties, Ala. (7).

OUTLOOK

Recent data indicate that diatomite production for various industrial uses has been steadily increasing at an average annual rate of about 5 percent. The demand for diatomite should continue, and a small but steady production increase can be expected.

Individual uses such as filtration, filter aid, industrial filters, insulation, and other miscellaneous uses have shown a steady or increasing demand since 1959. The abrasive use of diatomite is small and has steadily decreased; in time it may cease completely.

The increasing demand for diatomite may encourage exploration for new deposits and eventual exploitation of less desirable impure deposits.

Applied research by diatomite users and producers will continue to develop new applications for this nonmetallic mineral. Additional research and resource investigations may be carried out by the Bureau of Mines and the various agencies of diatomite-producing States.

Domestic reserves of diatomite are adequate for the forseeable future.

PROBLEMS

Shortage of high-grade diatomite deposits in the eastern and central sections of the country and lack of economical techniques to beneficiate low-grade diatomite are obstacles to the development of diatomite production closer to major consuming markets.

The high cost of transporting diatomite from the current major producing areas in the Western States to the principal markets in the highly industrialized Eastern and Central States remains a primary industry problem.

Potential newcomers in the industry are handicapped by the limited availability of information on methods of testing, beneficiation, and other technical data. Almost all research is sponsored by industry, and results are not published.

Processing problems occur in the industry which require the development of special techniques. The high ratio of water in some newly mined diatomites, the fragile character of the material, and the complex specifications required for the final product are examples of industry problems.

If rigid precautions are not observed, diatomite dust can cause pneumoconiosis among workers, especially in plant areas where dust from calcining operations is present (*1*, *3*).

FELDSPAR

By J. Robert Wells [1]

FELDSPAR production in the United States has grown with general industrial expansion since the commencement of the pottery industry in the 1850's. An alltime production high of 560,000 long tons of crude feldspar was reached in 1956.

Ten companies produce more than 90 percent of crude feldspar mined and market most of the feldspar sold in the United States. There are many small producers of crude feldspar, most of which sell to the larger producers and grinders. Feldspar deposits are widely scattered throughout the United States, but production is centered in the Southeast, New England, the Rocky Mountains, and California.

Feldspars are anhydrous aluminum silicates of potassium, sodium, or calcium in which one base generally predominates. Feldspar is ground to various mesh sizes and sold to the ceramic industry as a flux and as a source of alumina.

Feldspar and feldspathic rocks and sands are mined by various methods depending on the type of deposit. Pegmatite deposits with large crystals of feldspar are mined by small- and large-scale methods followed by hand cobbing and hand sorting, and by mass mining methods with subsequent flotation or electrostatic concentration. Feldspathic rocks are mined by large-scale methods and concentrated by flotation. Feldspathic sand deposits are mined by dragline excavators. Feldspar-silica mixtures are also produced as byproducts of granite quarrying by beneficiation of discarded fines.

Ore for flotation feed is crushed and wet-ground in rodmills to minus 20-mesh. Feldspar from sands is concentrated by flotation, but in some cases feldspar-sand mixtures are used directly in glass manufacture. Iron and iron-bearing minerals are removed from feldspar by magnetic separators; quartz and feldspar may be separated electrostatically, but the practicality of the process has not been proved. Most finely ground feldspar is dry ground in silex-lined pebble mills. The principal byproducts of feldspar mining are quartz and mica.

Feldspar is used principally as a flux in making glass, pottery, porcelain, enamel, tile, and other ceramic products.

Nepheline syenite and aplite are the major substitutes for feldspar as sources of alkalies and alumina. Other substitutes, depending on use, are talc and pyrophyllite.

Although nepheline syenite and some feldspar are imported from Canada, the United States is self-sufficient in feldspar. World reserves are adequate.

The outlook for the feldspar industry is for a gradual growth paralleling the gross national product with substitutes continuing to supply a significant part of the demand. Feldspar recovered by froth flotation has reached nearly 70 percent of the total domestic production.

The major problems of the industry are high production costs for hand-cobbed material, inadequate data on massive high-grade deposits, transportation costs, and competition from substitutes.

BACKGROUND

SIZE, ORGANIZATION, AND GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

Feldspar was first mined in the United States in North Carolina in 1744 and shipped to England. Earliest recorded production for local consumption was from a deposit in Connecticut in 1825, and the first feldspar mill was set up at the Toll Gate mine, south of Middletown, Conn., about 1850. Since then, the feldspar mining industry has expanded with the industrial growth of the country, and production of

[1] Commodity specialist.

crude feldspar reached the alltime high of 560,000 long tons in 1956. Since 1956 production has averaged 510,000 long tons per year.

The three leading feldspar companies supply 65 percent and the next seven firms supply 27 percent of marketable feldspar production in the United States. A large number of firms and individuals supply the remaining 8 percent. There has been a gradual consolidation and absorption of the smaller firms into the larger ones. Most of the small producers operate intermittently and sell their crude ore to larger producing companies or independent mills. A small quantity of crude ore is sold directly to consumers who grind it to their own specifications.

In 1940, a large-scale pilot plant operation of a froth flotation process developed by the Bureau of Mines indicated that greatly reduced production costs could be achieved for glass feldspar. This resulted in the first commercial flotation plant at Kona, N.C., in 1946. Ten froth flotation plants are now operated by seven of the large companies to recover feldspar concentrate from pegmatite and alaskite. Feldspar is recovered from California dune sands by two companies, one of which uses froth flotation. In 1963 about 66 percent of the marketable feldspar produced was recovered by froth flotation.

Feldspar concentrate is sold mostly to glass and pottery manufacturers, with about 5 percent going to other industries. Some of the companies employing flotation also produce feldspar from hand-cobbed or sorted ore (crushed and sorted on conveyor belts). Some companies produce only hand-cobbed or sorted ore. The smaller operators produce only hand-cobbed material.

Feldspar is mined in at least 35 countries. Owing to its wide distribution and low unit cost, feldspar trade between countries is not great. Leading free world producers in order of production are the United States, West Germany, Italy, France, Sweden, Norway, Japan, and the Republic of South Africa. U.S. mine production has been reported from more than half of the States, but production in 1959–63 was centered in North Carolina, California, Connecticut, Georgia, South Carolina, South Dakota, New Hampshire, Virginia, Arizona, and Maine, in order of production. Most grinding mills are in feldspar mining areas, and some are in the immediate vicinity of the larger mines. Some merchant grinders are in consuming areas.

DEFINITION OF TERMS, GRADES, AND SPECIFICATIONS

Feldspar is a term applied to a group of igneous minerals consisting chiefly of aluminosilicates of potassium, sodium, and calcium; one base usually predominates.

Orthoclase and microcline, the most common potash feldspars, have the same composition, $KAlSi_3O_8$, and differ only in crystalline form. Anorthoclase is a feldspar in which part of the potash is replaced by soda. A small quantity of anorthite may be present. The soda-lime feldspars, called the plagioclase group, form an isomorphous series with albite or "soda spar" ($NaAlSi_3O_8$) at one extreme and anorthite or "lime spar" ($CaAl_2Si_2O_8$) at the other. Anorthosite is a mixture of albite and anorthite.

Cornwall stone, imported from England, is a highly weathered and partly kaolinized feldspathic rock used to replace feldspar and kaolin in some ceramic applications.

Lithospar is a term used by the feldspar industry to designate a naturally occurring mixture of spodumene and feldspar.

Potash and soda feldspars both are used, but potash feldspars are preferred for most ceramic uses. Grades of feldspar are identified by their end use. Glass grade must be 99.5 percent through 20-mesh and must not contain over 0.05 percent iron oxide; amber glass grade may contain up to 0.50 percent iron oxide. Ceramic grades range from 120- to 325-mesh.

Some companies designate their products by number; the grade with the highest potash content is No. 1 and No. 2 is a lower grade. There may be two or more mesh sizes for one number; for example, No. 1, 230-mesh, and No. 1, 200-mesh. Some feldspars are designated by alkali content (the sum of K_2O and Na_2O present), and some by the alkali ratio (the ratio of K_2O to Na_2O in the ore). For some uses the free quartz content of the final product must be designated.

There are no rigid specifications for feldspar. Commercial Standard CS 23–30 by the National Bureau of Standards has received little acceptance (*10*).[2]

TECHNOLOGY

Geology

Feldspar may be white, grayish yellow, yellow, shades of red from light rose to brick, green, or bluish depending on impurities. It has a vitreous to pearly luster, an uneven fracture, and a hardness of 6.0 to 6.5 according to

[2] Italicized numbers in parentheses refer to items in the list of references at the end of this chapter.

Mohs' scale. The specific gravity is 2.54 to 2.76, the refractive index is 1.524 to 1.584, and the melting point is 1,100° to 1,522° C.

The feldspars are mong the most widely distributed of rock-forming minerals, and they occur as constituents of most rocks. Feldspar occurs in crystals large enough for selective mining only in dikes formed where the crystallization from molten magma has been slow.

Feldspar-bearing pegmatite dikes can range in width from stringers to masses over 100 feet across, and single crystals can be from several inches to several feet long. Occasionally, crystallization is exceptionally coarse or the constituents of the dike are separated into distinct zones. In such cases feldspar can be obtained in commercial quantities virtually free from associated minerals by simple hand sorting.

Quartz and muscovite mica are always associated with feldspar in dike deposits. Common accessory minerals include tourmaline, pyrite, biotite, hornblende, garnet, and magnetite, all iron-bearing minerals. Pegmatite may also contain such minerals as spodumene, beryl, columbite, tantalite, and cassiterite.

Granite sometimes contains as much as 60 percent feldspar as fairly coarse crystals. These crystals, however, often contain disseminated iron-bearing minerals which render the feldspar worthless for most commercial uses.

Alaskite is an igneous rock consisting essentially of quartz, mica, and feldspar intermingled in an irregular texture. The feldspar grain size is larger than that in the average granite, but alaskite seldom can be treated by hand picking. Three companies mine alaskite from a large deposit in North Carolina and beneficiate it by flotation to recover all three major constituents. The feldspar product is a mixture of potash and soda feldspar, the K_2O content ranging from 4 to 8 percent.

Commercially minable quantities of feldspar occur in some beach and river sands.

Mining

Feldspar deposits are mined chiefly by open-pit methods, although a few mines are underground.

Feldspar-bearing dikes are usually steeply inclined bodies with well-defined boundaries which can be worked with little or no removal of wall rock in the early stage of mining.

In zoned pegmatites, only the feldspar portions of the deposit are mined. Development usually proceeds from surface pits or from side-hill cuts, depending on the nature of the outcrop. Sometimes dikes with a long surface strike are mined by a series of pits opened simultaneously or successively on zones of clean feldspar. Exceptionally wide dikes are mined by underground methods after a moderate depth is reached by opencut methods.

Hand cobbing and sorting are employed at all small mines and at some large ones, not only to upgrade the feldspar but to select byproduct minerals such as mica and beryl before crushing; the smaller mines usually are worked intermittently. At the larger mines, crushers and picking belts are installed at the open pit, permitting the recovery of feldspar and associated minerals from ores that are too intimately mixed for hand cobbing.

Mining feldspar for subsequent treatment by flotation is simpler and cheaper than mining for other treatments, because mining need not be selective and fine fragmentation is not harmful. Most drilling is by wagon drills using 2½-inch bits, and larger rounds are blasted using 40 and 60 percent dynamite or ammonium nitrate. The ore is loaded by power shovels and transported by truck to the flotation plants.

Dragline excavators, loading bins, and trucks are used to recover feldspar from sand deposits.

Milling

Hand-cobbed or belt-picked ore is crushed, dried, and screened. Magnets are employed to remove tramp iron. The undersize goes first to mixing bins and then to silex-lined pebble mills for final grinding and sizing. Variations of this simplified flowsheet are in use.

In a typical North Carolina froth flotation plant (*7–8*), run-of-mine rock is reduced to minus 4 inches in jaw crushers and to ⅝ inch in gyratory crushers. The crushed rock goes to storage bins or to stockpiles from which millfeed is withdrawn as needed. Millfeed is wet-ground in rodmills in closed circuit with 10-mesh screens. Spiral classifiers are used to deslime the ore, the overflow going to waste. Deslimed pulp is conditioned with amine collectors, and most of the mica is removed by flotation in a rougher circuit. Some feldspar and quartz are floated with the mica at this point, and the froth product is recleaned to produce a salable mica byproduct. The pulp is again conditioned, and the heavy minerals in the feed (especially garnet, tourmaline, and hornblende) are floated, along with any remaining mica. This fraction is discarded.

Feldspar in the tailing from the heavy mineral scavenging circuit is froth-floated using an amine collector. The concentrate is cleaned, dried, and ground. The tailing from the final rougher circuit may be marketed as structural sand, or further purified and sold as glass sand.

Separation of feldspar from sand deposits requires only froth flotation and magnetic sepa-

ration without preliminary crushing.

The precentage of feldspar produced by each milling method is shown in table 1.

TABLE 1.—*Derivation of ground feldspar, by percent*

Year	Hand cobbed	Flotation concentrate	Feldspar-silica mixtures
1959	31	53	16
1960	30	55	15
1961	23	62	15
1962	23	66	11
1963	17	66	17

Electrostatic separation has been attempted on a commercial scale, but although technically feasible it was too expensive in the area where it was used. Recent articles indicate that research on electrostatic separation of feldspar in the U.S.S.R. has shown promise (*9*).

USES

Glass consumed about 56 percent; pottery, 30 percent; and enamel, 5 percent. Other ceramic uses and scouring soaps and powders accounted for the next largest percentages.

A small tonnage of carefully selected crude material was consumed in the manufacture of teeth for dentures. Small quantities also were used as a binder in grinding wheels and as a soil conditioner.

Poultry grit and roofing granules formerly accounted for 20 percent of the feldspar consumed but only minor quantities now go to these uses.

BYPRODUCTS AND COPRODUCT RELATIONSHIPS

Quartz and mica are important byproducts of the feldspar industry. Some feldspar mines were first worked for sheet mica. Feldspar flotation and electrostatic separation methods produce glass-grade quartz, an ideal byproduct, since quartz and feldspar are used by the same industries. Other accessory minerals of feldspar that have been marketed are amblygonite, beryl, cassiterite, columbite, hubnerite, lepidolite, pollucite, spodumene, tantalite, and wolframite. Gem stones seldom constitute a byproduct in the larger feldspar mines because large-scale operations normally destroy gem materials. In the smaller operations where hand cobbing and sorting are used, production of gem stones may be important. Some varieties of feldspar have been used for ornamental building stone and art objects.

ALTERNATE MATERIALS

Until 1930 imported Cornwall stone was the only competitor for domestic feldspar in the ceramic industry. There are now a large and growing number of alternate materials. Among these are nepheline syenite, aplite, talc, pyrophyllite, electric furnace slag, and lithospar.

Nepheline syenite is a granular igneous rock made up of nephelite ($K_2O \cdot 3Na_2O \cdot 4Al_2O_3 \cdot 9SiO_2$), potash feldspar (microcline), soda feldspar (albite), and minor accessory minerals such as mica, hornblende, and magnetite. Nepheline syenite permits lower firing temperatures and has been used in sanitary-ware bodies, floor and wall tile, electrical porcelain, vitreous bodies, glass, and porcelain enamels.

Aplite is a rock product, commercially mined in Virginia, composed principally of albite, zoisite, and sericite. It is used in container and flat glass batches.

Talc can replace feldspar primarily in dinnerware and wall-tile bodies. Pyrophyllite is used as a source of alumina in enamels and wall-tile bodies.

Electric furnace slag, a byproduct in the manufacture of elemental phosphorus, is used as a low-cost source of alumina in glass batches where color is not a prime consideration.

Lithospar is a naturally occurring mixture of spodumene and feldspar. It is used as a flux since the fusion temperature is much lower than that of either constituent alone.

Plastics have become prominent as replacements for dinnerware, tile, and other ceramic products containing feldspar. Aluminum tile is increasingly used in place of ceramic wall tile.

SECONDARY SOURCES AND RECOVERY

The most important secondary source of feldspar is scrap glass. The only other secondary source is garspar, the intimate mixture of finely ground glass and quartz produced by grinding and polishing plate glass with silica sand. It contains about 15 percent glass and 85 percent silica and consists mostly of minus 325-mesh materials.

RESERVES

Adequate resources of feldspathic ores exist in pegmatite bodies in the United States to provide for feldspar requirements for hundreds of years, but quantitative data are lacking. The largest developed areas in the East are the Spruce Pine district in North Carolina, the Keene and Grafton districts in New Hampshire, the Paris-Rumford and Topsham districts in

Maine, and the Middletown district in Connecticut. In the West, South Dakota has large areas of pegmatite occurrences in Custer and Pennington Counties, and in Colorado the Front Range has pegmatites over several hundred square miles. Large deposits of California beach sands in Monterey Bay contain about 50 percent feldspar.

Quantitative data on world reserves of feldspar are not available. The same general conditions hold true for foreign countries as for the United States. Vast resources are available from feldspathic rocks and sands in many parts of the world. Large commercial resources of feldspar occur in Canada. According to reports, 7.6 million tons of ore containing 59.2 percent feldspar has been blocked out on a 25-acre tract at Cape Feldspar, Quebec.

SOURCES OF STATISTICAL INFORMATION

Annual data on production and sales of crude feldspar are obtained from a canvass of domestic producers by the Bureau of Mines, and annual data on ground feldspar sold, on shipments by destination, and on uses are obtained by the Bureau from all known merchant mills in the United States. No canvass of users is made.

World production and trade data are also compiled by the Bureau. U.S. exports and imports are compiled from data supplied by the U.S. Department of Commerce.

PRODUCTION, CONSUMPTION, AND TRADE

The United States has been the world's leading producer and consumer of feldspar for about 70 years. In 1959–63, the United States accounted for 35 percent of world production. In 1959–63 the glass, pottery, and enamel industries consumed 90 percent of the ground feldspar sold by merchant mills (table 2). Table 3 shows the amount of feldspar shipped from U.S. mills in this period.

TABLE 2.—*Ground feldspar sold by merchant mills in the United States, by uses*

[Short tons]

Total	560,105	528,348	541,626	527,347	598,706

[1] Included with "Other destinations."

[2] Includes Alabama (1960–62), Arkansas, Colorado, Connecticut, Florida (1960–61), Georgia (1960 and 1963), Hawaii (1961), Kentucky, Louisiana, Maine (1959–60), Michigan, Minnesota, Mississippi, Missouri, Oklahoma, Rhode Island, South Carolina (1962–63), Tennessee, Utah (1960), Vermont (1960 and 1962–63), Virginia (1963), Washington (1959–62), shipments that cannot be separated by States, and shipments indicated by footnote 1. Also includes exports to Canada, Colombia (1961), Cuba (1959–60), England (1959 and 1962), Mexico, Panama, Philippines (1963), Puerto Rico (1959), and Venezuela (1959–63), and small quantities to other countries.

Owing to its wide distribution and low unit cost, feldspar has never been significant in world commerce. U.S. feldspar imports, essentially all from Canada, have declined from an annual average of almost 19,000 long tons during 1945–49 to about 4,000 tons per year in 1959–63. Tariff rates effective October 31, 1963, on feldspar were 12.5 cents per long ton on crude and 7.5 percent ad valorem on ground feldspar. World production of feldspar is shown in table 4.

[1] Feldspar is produced in China, Czechoslovakia, Republic of Korea, and Rumania, but data are not available; no estimates included in total except for Czechoslovakia.

[2] Data not available; estimate included in total.

[3] Estimate.

[4] In addition, the following quantities of aplite and other feldspathic rock were produced: 1954–58 (average), 72,871 tons; 1959, 88,451 tons; 1960, 91,339 tons; 1961, 132,041 tons; 1962, 168,543 tons; 1963, 211,172 tons.

PRICES AND COSTS

Crude feldspar prices do not appear in the trade publications. The average value of crude feldspar, computed from producers' reports to the Bureau of Mines in 1963, was $10.06 per long ton.

Feldspar prices were quoted in the E&MJ Metal and Mineral Markets in 1963 as follows:

North Carolina, bulk carlots, 200-mesh, $17 to $21 a short ton; 325-mesh $18 to $22, glass-grade feldspar $13.50; and 20-mesh semigranular $7.50 (add $3 a ton to bulk quotations for bags and bagging).

In 1963, computed from reports from merchant grinders to the Bureau of Mines, the average selling price of ground feldspar was $12.28 a short ton; the Illinois price was the highest, at $25.10.

TAXES

Producers of feldspar are granted a depletion allowance of 15 percent for both domestic and foreign production.

TRANSPORTATION

Feldspar is normally shipped by rail either in bulk or in 100-pound bags. Except for a few high-grade, high-value products it cannot be marketed far from its source because freight costs become excessive. Ocean shipping from Canada to the eastern seaboard commenced in 1957.

RESEARCH

Comprehensive studies have been made in recent years to obtain data concerning the effects of particle size of feldspar and quartz on processing characteristics and fired properties of porcelain and other ceramic bodies. New methods of processing feldspar ores have been developed, including methods for separating potash feldspars from soda feldspars. A number of new products requiring feldspar as a principal ingredient have been patented.

The Bureau of Mines has demonstrated the technical feasibility of recovering alumina from anorthosite and more recently has conducted beneficiation studies to determine the practicability of obtaining feldspar as a byproduct in processing pegmatites for recovery of beryl. A study was recently made by the Bureau on feldspar mining, processing, and marketing methods in the Eastern United States.

OUTLOOK

The principal outlets for feldspar are in the manufacture of glass, pottery, and enamel, so that the amount of feldspar produced reflects fluctuations in these industries and is further affected by the degree to which aplite and nepheline syenite are substituted in these applications. From consideration of projections of these influences and of historic trends it is expected that annual feldspar production, although at a relatively constant average level around 525,000 tons during the past decade, will increase to about 750,000 tons by 1980.

Flotation concentrates will continue to supply the major part of the feldspar and should account for about 75 percent of the total domestic output by 1980. Use of feldspar-silica mixtures should also increase at the expense of hand-cobbed material and should represent about 20 percent of the total feldspar produced by 1980. Hand-cobbed feldspar will probably constitute between 5 and 10 percent of the total.

Beneficiation methods should improve, and byproduct feldspar can be expected in increasing quantities from mining of other minerals in granitic and pegmatitic rock. Competition from aplite and nepheline syenite will continue in areas that can be served by producers in Virginia and in Ontario, Canada.

PROBLEMS

The feldspar industry faces a number of problems from factors that are beyond the control of the producers. The principal market for feldspar is the glass industry, which in turn is dependent on the automobile, construction, and container industries; changes or fluctuations in any of these are reflected in feldspar production.

Economic separation of the soda and potash feldspar components is an important problem because many ceramic users prefer the potash type in their body mixes. Removal of impurities, particularly those that affect the color or the melting point of the final products, is a continuing problem to the producers, because they must be able to furnish essentially the same quality product from year to year.

The small miner using hand-cobbing methods has the dual problem of increasing labor costs and price competition from flotation products. As a consequence the smaller producers are being forced out of business.

FERROALLOYS

By Gilbert L. DeHuff [1]

FERROALLOYS give various alloy steels their respective qualities, or serve important functions in the production of steel itself. The ferroalloy industry is closely associated with the iron and steel industry, its largest customer. The value of ferroalloy shipments for both 1962 and 1963 was about $390 million with tonnages approximating 2 million short tons annually. Approximately 30 companies engage in the production of ferroalloys, although some of these firms only produce ferroalloys as byproducts.

The principal ferroalloys are those of manganese and those of silicon. Manganese is used in the production of virtually all steel, primarily to neutralize the harmful effects of sulfur. Silicon is used primarily for deoxidization. Silicon and manganese have important alloying effects, also. Boron, chromium, cobalt, columbium, copper, molybdenum, nickel, phosphorus, tantalum, titanium, tungsten, vanadium, and zirconium are among the other elements contributing to the character of the various alloy steels.

One of the more important effects that these alloying elements impart is hardenability, or the depth to which the steel hardens. It has been determined that the use of a variety of alloying components increases hardenability at a greater rate than will equal additions of only one.

The principal information regarding the various ferroalloy elements is given in the respective commodity chapters of this volume. This chapter considers the interrelationships of the ferroalloys and the other aspects of the ferroalloying elements that cannot be covered adequately by individual commodity chapters.

BACKGROUND

The modern steel and ferroalloy industries began with Sir Henry Bessemer's discovery of the Bessemer process for making steel (1856). This was soon followed by Robert Mushet's introduction of manganese to make a sound, workable ingot. Manganese was virtually the only ferroalloying element used as an additive until the mid-1890's when ferrosilicon began to be used as a deoxidizer in place of ferromanganese. At about this time, the electric arc furnace was developed and applied to the production of ferroalloys. Among the first alloys to be made commercially in the electric furnace were ferrovanadium, ferrochromium, ferrotungsten, ferromolybdenum, and ferrosilicon.

SIZE, ORGANIZATION, AND GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

The ferroalloy industry is composed of approximately 30 companies. Two of these companies, Bethlehem Steel Co. and United States Steel Corp., are significant producers of blast-furnace manganese ferroalloys, in addition to being major steel producers. Although both companies produce ferromanganese primarily to satisfy the demands of their own steel plants, both companies sell the alloy to others. As may be seen from table 1, few of the 30 firms making ferroalloys approach a full range of the alloying elements among their products. The eight ferrophosphorus producers make ferrophosphorus only as a byproduct of their operations for the production of elemental phosphorus. They make no other ferroalloys.

Most of the domestic industry capacity is at plants east of the Mississippi River at points which are strategically situated with respect to consuming steel centers, cheap electric power, and favorable transportation.

Many foreign countries produce ferroalloys. While this industry formerly was confined chiefly to the large steel producing countries, in recent years the production from nations better known as producers of ferroalloying ore has become significant.

Woodward Iron Co	Woodward, Ala	FeSi (E).

[1] FeMn, ferromanganese; Spln, spiegeleisen; SiMn, silicomanganese; FeSi, ferrosilicon; FeP, ferrophosphorus; FeCr, ferrochromium; FeMo, ferromolybdenum; FeNi, ferronickel; FeTi, ferrotitanium; FeW, ferrotungsten; FeV, ferrovanadium; FeB, ferroboron; FeCb, ferrocolumbium; FeCbTa, ferrocolumbium-tantalum; FeZr, ferrozirconium.

[2] E–Electric; B–Blast; T–Thermite.

[3] Made by fused salt electrolysis.

[4] Includes Alsifer, simanal, ferrosilicon boron, and miscellaneous ferroalloys.

DEFINITIONS OF TERMS, GRADES, AND SPECIFICATIONS

The term "ferroalloys" is defined by Webster's New International Dictionary of the English Language (1961) as "a crude alloy of iron with some other metal, used for deoxidizing molten steel and making alloy steels." In practice, however, the term is used loosely to include alloys or compounds containing little or no iron, and even relatively pure metals, employed to introduce additive or alloying elements in the production of steel. "Addition agent" is perhaps a more correct terminology for covering all three groups (*24*),[2] although not as freely employed. In using the term "ferroalloys" in the treatment of its statistics, the Bureau of Mines goes beyond the strict definition, following the sense of the general Webster definition of the prefix "ferro-" as denoting the "presence of, or connection with, iron."

The prefix "ferro-" used specifically as linked to a particular alloying element designates an alloy of that metal and iron; for example, ferromanganese, ferrosilicon, or ferrochromium. The various ferroalloys in general, and these three in particular, are offered in a wide variety of grades, some of which combine two of the alloying elements as in silicomanganese or in ferrochrome silicon. In the case of ferrosilicon, as the silicon content drops below 20 percent the resulting alloy is called ferrosilicon by some, silvery pig iron by others. The latter grades down into what is essentially a high-silicon pig iron. Spiegeleisen may be considered a low-manganese ferromanganese, or a

[2] Italicized numbers in parentheses refer to items in the list of references at the end of this chapter.

high-manganese pig iron. European practice frequently has been to use ferromanganese of lower manganese content than in the United States—alloy that would be termed "off-grade ferromanganese" in this country.

Industry specifications for 14 ferroalloys are presented by the American Society for Testing and Materials (ASTM) (*3*).

TECHNOLOGY

About two-thirds of the total U.S. production of ferromanganese is made in blast furnaces, the remainder is made in electric furnaces. Virtually all spiegeleisen was made in blast furnaces, until a principal producer completed conversion to electric furnaces in 1963. Silicomanganese, medium carbon, low carbon, and special grades of ferromanganese are made in the electric furnace, as are ferrosilicon and the various regular grades of ferrochromium. The lower grades of silvery pig iron are made in blast furnaces; the higher grades, sometimes considered to be among the ferrosilicons, may be made in either electric or blast furnaces. The other ferroalloys are made in electric furnaces or by the thermite process. Special processes, such as aqueous or fused salt electrolysis or special vacuum furnaces, are used by some producers for production of certain of the higher quality alloys.

The blast furnaces making ferroalloys are the same as those used for making pig iron or are similar to them with modifications favoring the alloy production. Although not the usual current domestic practice, a furnace might have a run of sufficient length to produce the quantity of alloy desired and then be returned to its normal business of pig iron production.

Electric arc furnaces used for making ferroalloys may be the same as those for making calcium carbide, although to use the same furnace for both is not good practice. Certain ferroalloys, however, may be produced interchangeably in one furnace, and the practice is not unusual.

Although high-carbon ferroalloys, such as high-carbon ferromanganese, are made in quantity in the electric furnace, these furnaces are essential for large quantity production of the medium- and low-carbon grades of alloy. Production of the lower carbon and other special grades of alloy may employ a two- or even three-stage furnacing operation, depending on the specifications desired and the raw materials used.

Some of the less common ferroalloys and their metals are made by the thermite (thermic or Thermit) process wherein aluminum powder or shot, or some other finely divided highly active metal, is mixed with the ore and ignited. The alloying element of the ore is reduced, the oxygen of the ore transfers to the reacting metal, and heat of the reaction melts the charge.

In the production of virtually all steels, a manganese ferroalloy is employed to counteract the harmful effects of sulfur. The manganese addition acts as a deoxidizer as well. General practice, however, adds a silicon alloy for this purpose, or another deoxidizer stronger than manganese. In certain instances, silicomanganese is used as one alloy to accomplish both objectives.

The different ferroalloying elements may be grouped according to some of their principal functions, although certain of these elements are seldom used for the purpose specified, because of cost or other reasons, and two of the elements—sulfur and phosphorus—are ordinarily considered harmful:

1. To deoxidize—Silicon, aluminum, manganese, calcium, vanadium, titanium, and zirconium. Although manganese additions contribute to deoxidization of steel, the element is not ordinarily added for this purpose.
2. To neutralize sulfur—Manganese. Titanium and zirconium are effective, but are not used because of cost, relatively limited supply, and metallurgical problems.
3. To improve hardenability—Aluminum, boron, chromium, manganese, molybdenum, nickel, silicon, tungsten, vanadium, and others. Hardenability is the depth to which the steel can be hardened. Effects are greatly increased by use of a combination of different elements.
4. To improve corrosion resistance—Chromium, columbium, nickel, phosphorus, silicon, molybdenum, titanium, tungsten, and copper.
5. For special magnetic or electrical properties—Silicon, cobalt, nickel, chromium, and tungsten.
6. For high temperature applications—Chromium, cobalt, columbium, molybdenum, nickel, titanium, tungsten, and vanadium.
7. To improve machinability—Lead, phosphorus, selenium, and sulfur.
8. To increase strength—Chromium, molybdenum, silicon, vanadium, nickel, phosphorus, columbium, and manganese.
9. To refine grain—Vanadium, and aluminum.
10. For toughness—Nickel, vanadium, manganese, and molybdenum (*1,2,12,24*).

In improving hardenability the alloying effects are increased by using a number of different alloying elements in combination, and the effect of any one element on the properties of steel can not be determined independently of the others. The multiplying factor principle

or method for calculation of hardenability is based on experiments by Grossmann and others. It states in effect that, when two or more alloying elements are present in a steel, the total hardenability is affected by the product and not the sum of the hardenability effects of the individual alloying elements. Because manganese and silicon are almost invariably present in heat-treatable engineering and constructional steels, and both exhibit significant alloying effects although not necessarily added for that purpose, they must also be considered in any application of the formula developed by Grossmann (*1*, *11*, *14*, *16*, *24*).

An excellent example of the effects of the multiple-alloy principle was illustrated in the nickel-chromium-molybdenum steels widely adopted for engineering use during World War II. These steels, identified as the American Iron and Steel Institute (AISI) 8600 series, were known as triple-alloy steels although carrying 0.87 percent manganese and 0.28 percent silicon in addition to the nickel, chromium, and molybdenum percentages of 0.55, 0.50, and 0.20, respectively. The manganese and silicon were added to control sulfur and oxygen, but their alloying effect exceeds that of the three other elements combined.

It is not uncommon for six, seven, or eight different alloying elements to be included in the specifications for heat-treatable steels.

USES

The ferroalloys proper are used principally in the production of steel. In this context, they can be grouped in two more or less arbitrary categories: (1) those finding appreciable use in the production of carbon as well as alloy steels; and (2) those used solely or primarily in the production of alloy steels. The members of the first group may be important for the production of particular alloy steels, and some from the second group may occasionally be used in producing carbon steel.

The ferroalloys and the ferroalloy elements are also used by iron foundries, and by the nonferrous metal, chemical, and miscellaneous industries. Uses by the iron foundries are somewhat similar to those of the steel industry. The nonferrous metal, chemical, and miscellaneous industries tend to use a lesser proportion of the total as true ferroalloys, and more as compounds, master alloys (nonferrous), and metals of various degrees of purity. Among the more important uses outside the iron and steel industry are those for producing nonferrous high-temperature alloys, cryogenic alloys, magnet alloys, welding rods and coatings, cutting and wear-resistant materials, and for strengthening and hardening aluminum.

BYPRODUCTS AND COPRODUCT RELATIONSHIPS

All ferrophosphorus is produced as a byproduct resulting from the production of elemental phosphorus. Production of the alloy continues to exceed demand, creating an accumulation of large stocks. These stocks totaled 221,000 short tons at the end of 1963.

There are some limited coproduct relationships between other ferroalloys and base metals through the intimate association of the respective elements in a few ores.

CONSERVATION

From the discussion of technology, it can be seen that the steelmaker frequently has a choice of addition agents to achieve the effects desired. Under normal conditions, the choice is narrowed by cost, but in times of emergency short supply of one element often can be overcome by use of another. An exception is the use of manganese to counteract the effects of sulfur, and no satisfactory substitute has yet been found for it in the commercial production of steel in large quantities. Some conservation of manganese, estimated at not more than 5 or 10 percent, can be achieved by careful control of the production operation, if emphasis is not placed on costs.

SOURCES OF STATISTICAL INFORMATION

The Bureau of Mines annually collects production, shipment, and stock information from the ferroalloy producers on a voluntary basis. Data on consumption of all the common ferroalloys has been collected by the Bureau since January 1, 1959, on a monthly basis. In doing so, the iron foundries, nonferrous metal, chemical, and miscellaneous industries are covered in addition to the steel industry.

U.S. import and export statistics are compiled by the Bureau of the Census from data filed by the importer or the exporter with the Bureau of Customs. Foreign production data, not always readily available, are obtained annually by the Bureau of Mines from questionnaires sent to U.S. Consular offices abroad, whose principal sources of information are the official statistical releases of the particular foreign governments concerned. In many instances, the ferroalloys data are grouped together in one total rather than being treated individually.

PRODUCTION, CONSUMPTION AND TRADE

The domestic production and consumption of ferroalloys, as measured by shipments, vary with the production of steel ingots. Production and shipments are shown in table 2; consumption in tables 3 and 4.

Imports for consumption of ferroalloys are detailed in table 5; exports in table 6. Imports for a few of the ferroalloys in some years have been substantial in comparison with consumption. For certain years U.S. Government acquisitions under the Department of Agriculture's program for barter of surplus U.S. agricultural materials have been responsible for an appreciable portion of the larger quantities.

High-carbon ferromanganese was the largest ferroalloy import item in both quantity and value in 1949–63, except that in 1959 high-carbon and low-carbon ferrochromium both surpassed it in value. Medium-carbon ferromanganese, ferrosilicon, and silicomanganese are the only other ferroalloy imports that exceeded 10,000 tons in any year of the 1959–63 period.

TABLE 2.—*Ferroalloys produced and shipped from furnaces in the United States*

[1] Less than 1 ton.

Source: Bureau of the Census.

The only consistently large export by tonnage from 1950–63 has been ferrophosphorus. In the 1959–63 period, however, the value of exported ferrochromium exceeded that for ferrophosphorus in every year except 1963. In 1961 and 1962, the value of exported ferrosilicon was more than either.

The ferroalloys carry a variety of duty rates. Some of these are summarized in table 7.

TABLE 7.—*U.S. tariffs for various ferroalloy items*

Item	Duty rate 1 [1]	Duty rate 2 [1]
Ferrochromium:		
Not over 3 percent carbon	8.5 percent ad valorem	30 percent ad valorem.
Over 3 percent carbon	0.625 cent per pound contained chromium	2.5 cents per pound contained chromium.
Ferrosilicon chromium	10 percent ad valorem	25 percent ad valorem.
Ferromanganese:		
Not over 1 percent carbon	0.6 cent per pound contained manganese plus 4.5 percent ad valorem.	1.875 cents per pound contained manganese plus 15 percent ad valorem.
Over 1 percent but not over 4 percent carbon	0.9375 cent per pound contained manganese	1.875 cents per pound contained manganese.
Over 4 percent carbon	0.625 cent per pound contained manganese	1.875 cents per pound contained manganese.
Silicomanganese	0.9375 cent per pound contained manganese plus 7.5 percent ad valorem.	1.875 cents per pound contained manganese plus 15 percent ad valorem.
Spiegeleisen	75 cents per ton	75 cents per ton.
Ferromolybdenum	20 cents per pound contained molybdenum plus 6 percent ad valorem.	50 cents per pound contained molybdenum plus 15 percent ad valorem.
Ferronickel	1.25 cents per pound	3 cents per pound.
Ferrophosphorus	12.5 percent ad valorem	25 percent ad valorem.
Ferrosilicon:		
Over 8 percent but not over 60 percent silicon	0.8 cent per pound contained silicon	2 cents per pound contained silicon.
Over 60 percent but not over 80 percent silicon.	1 cent per pound contained silicon	3 cents per pound contained silicon.
Over 80 percent but not over 90 percent silicon.	2 cents per pound contained silicon	4 cents per pound contained silicon.
Over 90 percent silicon	4 cents per pound contained silicon	8 cents per pound contained silicon.
Ferrotitanium and ferrosilicon titanium	10 percent ad valorem	25 percent ad valorem.
Ferrotungsten and ferrosilicon tungsten	42 cents per pound contained tungsten plus 12.5 percent ad valorem.	60 cents per pound contained tungsten plus 25 percent ad valorem.
Ferrovanadium	12.5 percent ad valorem	25 percent ad valorem.
Ferrozirconium	12.5 percent ad valorem	25 percent ad valorem.

[1] Duty rate 1 is applicable for most nations; duty rate 2 is applicable for U.S.S.R., mainland China, and certain other specified Communist countries.

STRATEGIC CONSIDERATIONS

The U.S. ferroalloy industry has capacity in excess of present demand for ferroalloys, and for the immediate future under a peacetime economy. However, some of this capacity consists of outmoded plants and equipment which competition may force to close. Conceivably, under emergency conditions, the demand for certain alloys could tax the industry's ability to produce.

In its stockpiling program, the Government has established objectives for the following true ferroalloys: High-carbon, low-carbon, and silicon ferrochromium; ferrocolumbium; ferrotantalum columbium; high-carbon, and medium-low-carbon ferromanganese; silicomanganese; ferromolybdenum; ferrotungsten; and ferrovanadium.

In addition to stocks of ferroalloys, ample Government stocks of the most strategic ferroalloy ores or concentrate have been acquired.

With a few exceptions, notably ferrosilicon and ferromolybdenum, the United States depends on foreign sources of supply for raw materials. For those alloy stocks below the objectives, the deficiencies will be met by upgrading the raw materials held.

TABLE 8.—*Ferroalloys in Government inventories, June 30, 1964*

[Short tons]

	National (strategic stockpile)	CCC stocks and supplemental stockpile	Total
High-carbon ferrochromium	126,171	260,081	386,252
Low-carbon ferrochromium	127,740	188,647	316,387

PRICES

In the ferroalloy pricing, there is for most items a fairly wide price range depending upon sizing, quantity, and method of packaging. This is in addition to the differences attributable to the different grades of alloy as determined by analysis or other special features. Ferroalloy prices are subject to rather wide fluctuations, but usually the price changes are selective. However, a price change for one alloy may affect prices of others.

The price relationships among several of the alloys may be obtained from table 9. Actual prices in many instances as quoted are nominal.

TABLE 9.—*Ferroalloy prices for bulk quantities, December 1963*

Ferroalloy	Grade	Dollars per pound
Ferrochromium	High carbon	[1] 0.19
Ferrochromium	Standard low carbon, 67 to 73 percent chromium.	[1] .225
Ferrocolumbium	50 to 60 percent columbium	[1] 3.00
Ferromanganese	Standard high carbon	.085
Silicomanganese	Maximum 1½ percent carbon	.078
Spiegeleisen	19 to 21 percent manganese	.038
Ferromolybdenum	55 to 65 percent molybdenum, powdered.	[1] 1.95
Ferrophosphorous	24 percent phosphorous	.054
Ferrosilicon	50 percent silicon	[1] .121
Ferrotitanium	Low carbon	[1] 1.35
Ferrotungsten	70 to 80 percent tungsten	[1] 1.75
Ferrovanadium	Open hearth, 50 to 55 percent vanadium.	[1] 2.85

[1] Per pound contained significant element.

TRANSPORTATION

Most ferroalloy plants are near consuming centers and transportation of the finished product seldom presents a problem. Only for those plants in the Western States near ore sources would the transportation costs seriously limit the market area. In past emergencies the transportation of foreign ores has posed a serious problem. Hopefully, the subsequent location of U.S. Government stockpiles near consuming centers has solved this problem for the United States.

RESEARCH

Research on ferroalloys is conducted by members of the ferroalloy industry, steel companies, and the Bureau of Mines. These organizations have cooperated in steel research, benefiting both industries. Their research activities have led to reduction of steelmaking costs, reduction of ferroalloy production costs, development of new alloys, and the improvement of processes and products. Research plays a prominent role in the relative competitive position of the various alloys.

Much of past Bureau of Mines research has been concerned with the development of procedures for utilizing low-grade or off-grade domestic ores for the production of standard or special alloys. The Bureau is interested in basic research, however. Both the Bureau of Mines and private industry have endeavored to find a substitute for manganese to counteract the effects of sulfur, but the only probable substitutes have more disadvantages than manganese—problems of both supply and metallurgy which make them unattractive for commercial use on a large scale.

OUTLOOK

Growth of the ferroalloy industry roughly parallels that of steel. Individual ferroalloys fluctuate in demand due to the interchangeability of many of the ferroalloys, but majority of the output will continue to be the alloys of manganese and silicon.

More ferroalloy research will be necessary to produce the best ferroalloy at the least cost for the specific needs created by the increasingly wider variety of alloy steels and new technological developments in steelmaking.

To meet this challenge, the industry will continue to replace its less efficient, high-cost plants with the most modern automated equipment and methods.

PROBLEMS

Perhaps the most serious problem of the ferroalloy industry is limited control over its own fortune because of dependence on the steel industry.

Many ferroalloys are produced in electric furnaces and the producers make long-term electric power contracts to obtain favorable power costs. This leads to overproduction at times of low demand for the ferroalloy product, or relatively high fixed charge for an idle plant.

Overcapacity is a worldwide problem, resulting in keen competition for the world's markets. The emergence of relatively undeveloped ore-producing countries as producers of alloys has aggravated the problem. Domestically, however, overcapacity can be misleading in part since inefficient, outmoded plants and equipment are maintained in standby condition because of existing power contracts or in anticipation of a surge in demand.

Low-profit margins result from the lower prices needed by the domestic producer to meet the competition for restricted markets from foreign imports, in addition to his domestic competition. These low-profit margins limit funds for research and engineering development required for the growth of the industry.

The keen competition, together with the highly specialized operation combining art and science needed to manufacture ferroalloys, results in a lack of published technological information. This slows the advance of ferroalloy technology.

The industry's trained personnel, both professional and nonprofessional, acquire valuable skills. When such personnel are lost, replacements must be trained which requires time.

Certain alloys deteriorate in storage over a period of years causing stockpiling problems. Knowledge concerning behavior of the different alloys under various conditions of long-term stocking is spotty, inconclusive, or completely lacking. The question of stockpiling ferroalloys is also difficult because changing technology and its effects are hard to foresee. Hence, there is a problem in deciding the quantity and kind of alloy to be stocked, or whether a particular commodity should be stored in alloy form at all. If stocks are held only as ore, then insufficient processing capacity or the concentration of productive capacity in likely enemy target areas becomes a problem of supplying the needed alloy in time of emergency.

FLUORINE

By Paul M. Ambrose [1]

FLUORINE is used in one ore form, fluorspar (CaF_2), mainly in the steel, glass, and enamel industries; in its principal acid form hydrofluoric acid (HF), for the manufacture of aerosols, refrigerants, and plastics; and in a natural and manufactured form, cryolite ($3NaF \cdot AlF_3$), as a flux in the electrometallurgy of aluminum.

Fluorite (CaF_2), commonly known in commerce by its rock name fluorspar, is the principal fluorine bearing mineral. Natural cryolite (Na_3AlF_6) has a higher fluorine content, but its occurrence is almost unique. The only known deposit of commercial tonnage is at Ivigtut, Greenland, and the total supply is relatively small. Phosphate rock often contains 2.5 to 3.5 percent fluorine and is potentially a large source.

Although the United States has been the world's largest fluorspar producer, domestic consumption far exceeds output, and over half the supply is imported. Most of the fluorspar produced in the United States is mined in an area along the Ohio River in southern Illinois and western Kentucky. This district also contains most of the domestic reserve. Capacity in the West has increased in recent years, particularly in Montana and Nevada, and in the future a larger portion of domestic output is expected to be produced in this area. Italy, Mexico, and Spain are the principal foreign sources.

In 1963, the largest use of fluorspar was for production of hydrofluoric acid which in turn was used as a catalyst in the production of high-octane gasoline. Hydrofluoric acid was also used to produce synthetic cryolite, aluminum fluoride, and many other fluorine compounds, including fluorocarbons for aerosols, refrigerants, and plastics. The second largest use of fluorspar was as a flux in steelmaking by the basic open-hearth, electric-furnace and basic oxygen methods. The third major use was in the manufacture of glass and enameled products. There are no adequate substitutes for fluorine in any of its major industrial uses.

Potentially a large alternative source of fluorine exists in wastes evolved in processing phosphate rock to produce fertilizers and other phosphate products, but to date commercial recovery of fluorine from phosphate rock in forms suitable for widespread industrial use has been on a relatively small scale.

The outlook is for increased consumption of fluorspar, particularly as a source of fluorine for the chemical industry and as a slag thinner in making steel. A long-range expansion in domestic output also may occur, but producers are confronted with major cost and quality problems in competing in the present market.

Some producers in the Illinois-Kentucky district must pump large quantities of water from the mines, adding substantially to production costs. Other problems include the need for more efficient recovery at reduced costs, increased recovery of byproducts, processes for utilizing lower grade and complex ores, the development of wider markets for flotation concentrates, and the need for additional information on resources.

BACKGROUND

Fluorspar has been known for centuries and was first used for ornamental slabs and ornaments that were carved from large crystals. Its usefulness as a flux was known in the 16th century. Mining started in England about 1775 and in the United States after 1820. There was substantial production before 1900 following the introduction of the basic open-hearth furnace in the steel industry. Production and usage increased with the growth of the steel industry and the introduction of a series of fluorocarbons useful as aerosols and refrigerants. Some of the fluorocarbons can be polymerized to make plastics.

[1] Commodity specialist.

The Illinois-Kentucky district has been the largest producer of fluorspar in the world but production for U.S. consumption has been surpassed by output from foreign sources, mostly from Mexico.

SIZE, ORGANIZATION, AND GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

There are approximately 26 fluorspar mines in the United States and about 11 mills. Most domestic production is contributed by about six companies having both mines and mills. Over half of the independent mines are small operations, producing only a few hundred tons a year which are sold to firms that operate mills or infrequently to consumers either directly or through brokers. The major independent and captive producers often supplement their mill requirements with ore purchased from small operators. Most of the domestic fluorspar operators are independent operators; however, in the acid segment of the industry there are three major firms that produce for their own consumption and one firm in the metallurgical phase of the industry. In 1963 the three firms accounted for about 64 percent of the total acid-grade output. Shipments of domestic fluorspar in 1963 totaled 200,000 tons valued at $9 million.

In the United States a small area in Hardin County, Ill., along the Ohio River accounted for about 66 percent of the total domestic shipments in 1963. Smaller tonnages were shipped from mines or mills in Colorado, Kentucky, Montana, Nevada, and Utah. Mills in Delaware and Texas processed foreign material. Principal producers of crude and finished fluorspar in the United States during 1963 are shown in table 1.

Production of fluorspar in Canada is centered chiefly in the St. Lawrence district on the Burin Peninsula in the Province of Newfoundland. There is a small fluorspar output from the Madoc area in Ontario.

The fluorspar mines in Mexico are scattered widely in the States of Chihuahua, Coahuila, Durango, Guerrero, Mexico, San Luis Potosi, and Sonora. A large part of the fluorspar has been produced by hand labor chiefly from surface workings, and has been hand sorted to yield a premium product. However, since about 1950, flotation plants and heavy-medium units have been installed by American organizations.

The fluorspar deposits in West Germany are in Baden and Bavaria. The mines in Baden are near Pforzheim and Schwarzwald. The principal Bavarian mines extend about 12 miles from Schwarzenfeld to Nabburg, but the Stulln-Nabburg-Woelsendorf area supplies the greater part of the output. The West German fluorspar mines are well developed and are served by modern milling plants, but reserves are being depleted.

Fluorspar occurs in the Italian Provinces of Lombardy, Trento, and Venetia, and on the Island of Sardinia.

TABLE 1.—*Principal producers of finished and crude fluorspar in the United States in 1963*

Producer	Location of milling plant		Grade
	County	Nearest town	
Colorado:			
Allied Chemical Corp., General Chemical Division	Boulder	Boulder	Acid.
Illinois:			
Aluminum Co. of America	Hardin	Rosiclare	Do.

Willden Bros	do	do	Do.

In Spain the principal mines are in the Provinces of Barcelona, Cordoba, Gerona, and Oviedo. The Caravia and Collada mines in the Province of Oviedo and the Osor mine in the Province of Gerona are the largest producers.

The entire world supply of crude natural cryolite comes from Ivigtut, Greenland. The Danish State owns the deposit, and the Kryolitselskabet Oresund Ald, Copenhagen, has the mining concession. There is no reserve of cryolite in the United States; however, in 1963 synthetic cryolite was produced by Kaiser Aluminum & Chemical Corp. at Chalmette, La., and Ravenswood, W. Va.; and by Reynolds Metals Co. at Bauxite, Ark. In the same year cryolite was reclaimed from pot linings by Aluminum Co. of America at Point Pleasant, Tex.; by Kaiser Aluminum & Chemical Corp. at Chalmette, La., Spokane, Wash., and Ravenswood, W. Va.; and by Reynolds Metals Co. at Listerhill, Ala., and Longview, Wash.

Fluorspar was used in 37 of the 50 States in 1963. The consumption pattern is shifting. Five years earlier 36 percent of the fluorspar was consumed in Illinois, Ohio, and Pennsylvania. These same States used 24 percent of the fluorspar in 1963.

DEFINITION OF TERMS, GRADES, AND SPECIFICATIONS

Fluorspar commonly is marketed in three grades—metallurgical, ceramic, and acid. Acid grade contains the highest percentage of CaF_2, metallurgical grade is the lowest, and ceramic grade is considered to be in between.

Metallurgical-grade may be sold in the form of gravel, lump, artificial pellets, or fine flotation concentrate. The lowest acceptable metallurgical grade normally contains at least 60 percent effective calcium fluoride. The usual standard on which prices are published contains 72.5 percent effective CaF_2. The effective value is determined by subtracting from the contained CaF_2 2.5 percent for every percent of silicon dioxide (SiO_2) present in the complete analysis.

Ceramic-grade fluorspar specifications differ substantially according to the requirements of individual buyers. It usually is finely ground and the CaF_2 content ranges from 85 to 97 percent with the bulk of the remainder being SiO_2 and calcium carbonate ($CaCO_3$). A limit usually is placed on iron oxide (Fe_2O_3).

Acid-grade fluorspar should contain a minimum of 97 percent CaF_2, and some specifications contain limitations on SiO_2, $CaCO_3$, and sulfide sulfur.

Chemical and physical requirements of acid-grade fluorspar were set forth in National Stockpile Material Purchase Specifications P–69a, dated February 13, 1952, by Defense Materials Service (DMS), General Services Administration (GSA).

National Stockpile Purchase Specification P–69b–R dated December 2, 1963, contained requirements for metallurgical-grade fluorspar acquired by DMS for the stockpile.

TECHNOLOGY

Geology

In the Illinois-Kentucky district the country rock is limestone, shale, and sandstone. Fluorspar occurs as veins along faults ranging in thickness from a mere film to a width of more than 30 feet and in extensive flat-lying replacement-type deposits in limestone. Residual deposits resulting from weathering of fluorite-bearing veins also are fairly common in the district and often indicate the presence of vein deposits at greater depth (*8*, *15*, *32–33*).[2]

In the Western States fluorspar occurs under a wide variety of conditions—as fillings in fractures and shear zones forming more or less well-defined veins and as replacements in the country rock. Much occurs in igneous formations (*7*, *13–14*, *24*, *28*, *30*).

At Ivigtut, Greenland, the cryolite is associated with pegmatite within an intrusive mass of porphyritic granite. Associated minerals are silica, fluorspar, galena, pyrite, and siderite.

Mining

Fluorspar mining is, in many respects, similar to the mining of metalliferous deposits in steeply dipping veins or in flat-lying deposits. Mining is done by shafts, drifts, and opencuts.

Shaft mines differ greatly in size, capacity, methods of working, and efficiency. At prospect shafts not over 50 feet deep, the simplest mining method may be employed with little other hoisting equipment than a hand-operated windlass and a bucket. At small mines more than 50 feet deep, single-compartment shafts with wood headframes are used; the ore is loaded at the face and trammed by hand on narrow-gage tracks to the shaft, through which it is hoisted by single-drum hoists powered by gasoline engines.

At larger mines the main shafts usually include two hoisting compartments and a manway compartment containing a ladder, air and water pipes, and electric-power conduits. Steel headframes generally have been adopted, and hoisting is done with double-drum hoists with

[2] Italicized numbers in parentheses refer to the items in the list of references at the end of this chapter.

skips or cages. Mining methods follow the practice of metal mines, adopting the method best suited to conditions. Top slicing, cut-and-fill, and shrinkage and open stoping are among the methods commonly used. Bedded deposits are usually worked by a room-and-pillar system. Some of the larger mines are extensively mechanized, using diesel-powered hauling and loading equipment (*1–2, 21–22, 25–26*).

At many fluorspar mines, water pumping is a major element in the mining operation. Large quantities of water enter the mines in the Illinois-Kentucky district through channels in the limestone and from the Ohio River. At the Rosiclare mine, for example, underground water flowed into it at a rate of 7,000 gallons per minute. The Crystal mine in the Cave in Rock area in Illinois has a water problem. When the "Big Sink," a landlocked area covering about 800 acres, rises to a high level because of excessive rains, water seeps into the mine from innumerable underground crevices and fissures and causes it to flood.

Milling

Although some domestic fluorspar is sold with little or no processing after mining, most crude ore requires beneficiation to yield a finished product. Milling practices range from rather simple methods, such as hand sorting, washing, screening, and gravity separation by jigs and tables, to sink-float and froth-flotation processes. Most of the domestic output is produced by sink-float, froth flotation, or a combination. These processes permit utilization of lower grade ore; recovery is much more efficient; and the finished product is of higher quality. Also, the flotation process permits recovery of the lead and zinc minerals often associated with the fluorspar ores (*1, 12, 25, 32*).

To a large extent the selection of a milling process depends on the character of ore to be treated and the type of product desired. Some highly disseminated ores can be treated successfully only by flotation, since fine grinding is necessary to liberate the component particles. Flotation also is commonly used where a pure product of fine particle size is desired, such as ceramic- and acid-grade fluorspar (*23, 34*). The heavy-medium or sink-float process is usually employed where a coarse product, such as metallurgical-grade gravel, is desired, and enough concentration can be achieved without fine grinding (*20*). Some producers use both processes in combination, producing gravel products by sink-float and treating undersize from the heavy-medium mill by flotation; or alternatively, sink-float is used to produce a preconcentrate, which is then used as feed for the flotation plant (*10–11*). There are now seven plants in the United States with facilities for making bricks, briquettes, or agglomerated products from fluorspar fines.

Flotation and other mineral-dressing techniques are employed to treat cryolite.

Chemical processes may be used to recover fluorine from phosphate rock. At present the greater part recovered is in the acidulation step in producing ordinary superphosphate. The fluosilicic acid is sold or used to prepare salts such as ammonium, magnesium, and zinc fluosilicates and sodium silicofluoride. A small tonnage of fluorine in the form of synthetic fluorspar was recovered by the Tennessee Valley Authority (TVA) from stack gases evolved in processing phosphate rock. The recovery process consists of absorbing the fluorine, which is present as hydrogen fluoride, in a bed of lump limestone at temperatures above the dew point of the stack gases. The calcium fluoride reaction product separates from the limestone lumps in the form of fines; portions of the bed are withdrawn from the tower at intervals and screened to remove the fines, and the oversize (partly reacted limestone) is recycled to the tower with fresh limestone (*16, 17, 19*). Because of the cost of purifying fluorine compounds recovered in processing phosphate rock most of the fluorine is neutralized and discarded.

USES

Fluorine is used principally in the form of fluorspar, cryolite, hydrofluoric acid, and fluosilicates.

Until recently the largest use of fluorspar has been as a flux in the manufacture of basic open-hearth, basic electric furnace, Bessemer converters, and basic oxygen steel furnaces. Many other metallurgical operations including the production of iron castings, ferroalloys, and nickel and its alloys; the melting and casting of aluminum and magnesium; the smelting of secondary metals; and the manufacture of fluxing compounds utilize small tonnages of fluorspar. Metallurgical operations consume fluorspar in gravel form, and flotation concentrate has been utilized to a limited degree. The use of pelletized flotation concentrate has not attained wide acceptance in the metallurgical industries, but is now receiving a great deal of attention for use in basic oxygen steel furnaces.

In recent years the greatest use has been in the production of hydrofluoric acid, an essential raw material in manufacturing synthetic cryolite and aluminum fluoride for the aluminum industry, and in many other applications in the chemical industry particularly in the

production of fluorcarbons for aerosols, plastics, and refrigerants. Acid-grade spar requirements of the aluminum industry have expanded rapidly in recent years and parallel the expansion in aluminum production. Cryolite, which serves as an electrolyte in the electrolytic reduction of alumina, is required in large quantities to fill reduction cells when new aluminum-production units are started; and in regular reduction operations cryolite consumed must be replaced by additional cryolite or aluminum fluoride. Based on 1951 data, it was estimated that 47 pounds of cryolite and 58 pounds of aluminum fluoride were consumed per ton of virgin aluminum produced (*3*, p. 7). The largest use of cryolite is in the production of aluminum. The quantity of fluorspar needed to produce a unit quantity of aluminum is being decreased because of increased reclamation of cryolite from pot linings. Smaller quantities are used in abrasives, insecticides, glass, and enamel.

Hydrofluoric acid is used by industry as a source of fluorine to produce refrigerants, propellants, fluorocarbon plastics, and other fluorine compounds; as a catalyst in the production of high-octane aviation fuels; in etching and polishing glass, pickling steel, cleaning metal castings, and enamel stripping; as a laboratory reagent; and for many other industrial uses. An important use for hydrofluoric acid is in the field of atomic energy to produce uranium tetrafluoride from uranium oxide. The tetrafluoride is used in preparing uranium hexafluoride. The most volatile compound of uranium, uranium hexafluoride, has been extensively utilized in the separation of uranium isotopes by thermal diffusion.

The third major use of fluorspar is for ceramic purposes in the manufacture of opal and flint container glass and as an ingredient in enamels for coating steel and cast iron. Ceramic-grade material also is consumed for welding-rod coatings, fiber-glass production, and as an additive to brick clays.

Small quantities of ceramic- or acid-grade fluorspar also are consumed by the magnesium industry.

Small quantities of clean, virtually colorless, and flawless crystalline fluorite have been used in lenses or prisms of microscopes, telescopes, and spectroscopes, but synthetically grown crystals have largely displaced fluorite in these uses.

Markets for the fluosilicates are relatively limited. Fluosilicic acid is used as a disinfectant in the brewing industry, as a preservative, in electroplating, as a concrete hardner, and in the manufacture of silicofluoride salts. Sodium silicofluoride is used for fluorination of community water supplies. In 1963 more than 43 million people in 2,300 towns used fluoride-treated water. Sodium silicofluoride and ammonium fluosilicate are used in insecticides, laundry applications, fluxing, ceramics, and casting light metals. The magnesium and zinc fluosilicates are used as concrete hardeners, and the magnesium salt also finds application in magnesium foundries.

BYPRODUCTS AND COPRODUCT RELATIONSHIPS

Lead, zinc, and minor quantities of other metals, such as silver, cadmium, and germanium, are often recovered as byproducts or coproducts of fluorspar. The value of lead and zinc produced in the Illinois-Kentucky area in recent years has been substantial. These byproducts are important factors in the economy of many fluorspar operations.

ALTERNATE MATERIALS

No suitable materials to replace metallurgical-grade fluorspar are available. However, blended fluxes using fluorspar as a base are used at some foundries.

The sulfuric acid process for producing high-octane components for gasoline can be used in place of the hydrofluoric acid process; however, the equipment for one acid process does not readily lend itself to the use of the other acid.

There is no satisfactory substitute for fluorspar in the manufacture of hydrofluoric acid.

Owing to its limited occurrence, much of the cryolite consumed in the United States is in the form of synthetic cryolite usually made by reacting sodium aluminate with hydrogen fluoride obtained from acid-grade fluorspar (*27*).

SECONDARY SOURCES AND RECOVERY

At some aluminum plants fluorine compounds are recovered and reused in the aluminum-reduction process.

RESERVES

Fluorspar reserves in the United States were recently estimated by the Federal Geological Survey to total 22.6 million short tons containing 35 percent or more CaF_2 or the equivalent value in combined fluorspar and metallic sulfides (*9*). An additional 12 million tons of lower grade material containing 15 to 35 percent CaF_2 was estimated. The reserve is larger than had been previously estimated by the Geo-

logical Survey because of better reserve information and because it includes substantial quantities of ore found in the last few years. The reserves of Newfoundland have been estimated (*15*) and some information on those containing more than 35 percent CaF_2 in Western Europe, and in the U.S.S.R. and its satellites, was given (*18*). The reserves and grade of fluorspar deposits in Mexico were reviewed in 1960 (*31*).

Information on grades and deposits has been compiled from the Federal Geological Survey, from Hose, from Chermette (*4, 5*), from other sources, and from recent unpublished data on deposits in France. The quantity of ore mined since the last estimate, was deducted from this composite information, and the new estimate of reserves and probable grade is as follows:

	Quantity (million short tons)	*Probable grade or range (percent CaF_2)*
Country:		
United States	18.2	40
Canada	5.0	70–75
Mexico	19.3	65
France	5.0	60–95
Italy	3.1	25–78
Spain	6.5	60–90
United Kingdom	1.7	46–96
West Germany	4.3	35
North Africa	3.3	30–40
South Africa	3.3	[1]
Sino-Soviet bloc	13.2	[1]
Others	4.4	[1]
Total	87.3	

[1] Data not available.

The United States has an enormous reserve of phosphate rock and some authorities have estimated its fluorine content to be equivalent to about 900 million tons of fluorspar. However, recovery of any substantial quantity of this fluorine depends upon the quantity of phosphate rock mined and sold, upon the treatment processes to which the phosphate rock is subjected, and upon further development of economic methods of recovering the fluorine in the desired commercial forms.

No estimate of the cryolite reserve in Greenland is available, but recent reports indicate that exploration has failed to develop appreciable new reserves, and the deposit may be approaching depletion.

SOURCES OF STATISTICAL INFORMATION

Annual and quarterly data on production and shipments of fluorspar are obtained from domestic producers by the Bureau of Mines. Over 95 percent of the consumers of all grades of fluorspar are canvassed quarterly. A biennial consumer canvass covers virtually all of the known consumption. All known importers of fluorspar are canvassed annually for imports and sales by quantity and use. World production and trade data are compiled by the Bureau from numerous sources. U.S. exports and imports are obtained from the U.S. Department of Commerce.

PRODUCTION, CONSUMPTION, AND TRADE

The growth of the fluorspar industry in the United States during the present century has been rapid, particularly since 1941. Annual production increased from an annual average of about 40,000 short tons in the decade 1900–9, to an average of about 323,000 tons during the decade 1940–49. During the same period, average annual imports increased from about 15,000 tons to 57,000 tons. From 1950 to 1963 domestic shipments of finished fluorspar fluctuated from 347,000 tons in 1951 to a low of 185,000 tons in 1959. During the same period there was a tremendous increase in imports of fluorspar from abundant sources in Mexico.

Domestic fluorspar production in 1963 (shipments from mines and mills) totaled 200,000 short tons. As a whole domestic fluorspar has been supplying a declining fraction of the market in recent years. Difficulty in meeting specifications required by buyers and the competition of foreign fluorspar are among the factors which have influenced trends in the industry. Shipments by States with maximum shipments in any year and cumulative shipments to the end of 1963 are shown in table 2, and consumption by States in 1963 is shown in table 3.

Because of lower production costs, and the availability of high-grade ore particularly in Mexico, consumers have generally found the use of foreign ore to be less costly than that from domestic mines.

Imports of fluorspar for several years were greatly stimulated by the strong demands of the consuming industries and the requirements of the national stockpile. Recently, industrial needs have been sufficient to require continued imports of large quantities. In 1963, imports totaled 555,000 short tons valued at $14.1 million, whereas 631,400 tons entered in 1957, 181,300 tons in 1951, and 2,100 in 1942. Mexico has recently been the principal source with several European countries shipping substantial tonnages.

Since 1952, imports have exceeded domestic production and in 1957 a record high of 631,367 short tons was recorded. Mexico has supplied the major quantity of the total fluorspar imported in recent years. In 1963, 80 percent of the imports of fluorspar were from

		West Virginia	43,411
		Total	736,350

Mexico. Italy and Spain have supplied all but a small part of the remainder. European fluorspar generally enters at Philadelphia; Canadian at Buffalo, Cleveland, New York, and Philadelphia; and the Mexican at Douglas, Ariz., and Brownsville, Eagle Pass, El Paso, and Marathon, Tex. Imports are shown in table 4.

Tariff rates in effect in December 1963 on fluorspar containing more than 97 percent CaF_2 was $1.875 per short ton ($2.10 per long ton) and less than 97 percent CaF_2 was $7.50 per short ton ($8.40 per long ton).

There is no tariff on cryolite.

During the 2½ years Public Law 733 was in existence, the domestic producers had shipped 156,603 short tons valued at $8,477,202 to the supplemental stockpile.

Increased consumption of fluorspar in the United States has been principally a result of growth in the requirements of the steel and aluminum industries, and increased use of fluorine chemicals. Consumption statistics by uses are shown in table 5.

1 Glass, enamel, and other (including welding rod coatings, nonferrous, special flux, and ferroalloys), partly estimated from sample canvass of consumers who accounted for more than 95 percent of total usage in 1959.

According to latest export statistics about 42 percent of the fluorspar produced throughout the world in 1963 entered foreign trade (see table 6).

STRATEGIC CONSIDERATIONS

Until recent years the United States, the largest consumer of fluorspar, had been able to provide the bulk of its needs from domestic mines and mills; however, recently the consuming industry has expanded at a rapid rate and imports in 1963 provided about three-fourths of the total fluorspar consumed. The proportion provided by imports is expected to increase. As consumption is expanding more rapidly than domestic production the United States has become less self-sufficient in fluorspar supplied, although ample reserves are available for development.

The strategic stockpiles are intended to supplement domestic production in time of emergency, when some foreign sources would not be available to this country. Ample stocks of acid-grade fluorspar were readily accumulated, but difficulty was encountered in building up metallurgical stocks. On June 30, 1964, Government inventories of acid-grade fluorspar totaled 1,144,100 tons, of which 458,100 tons was in the national (strategic) stockpile, 17,300 in DPA stocks, and 668,700 in the supplemental stockpile. Stocks of metallurgical-grade totaled 412,200 tons, of which 369,400 was in the national (strategic) stockpile, and 42,800 in the supplemental stockpile.

GOVERNMENT PROGRAMS

Under authority contained in Public Law 701 of 1958, the Office of Minerals Exploration was created on July 1, 1958, to provide Federal financial participation in the exploration for new mineral reserves. The Government will contribute 50 percent of the total allowable cost of the exploration work specified by the terms of the contract.

PRICES AND COSTS

Market price quotations on domestic and foreign fluorspar are regularly published in E&MJ Metal and Mineral Markets and in Steel magazine and quarterly in the Chemical and Engineering News magazine. In the Oil, Paint and Drug Reporter, prices that indicate

[2] Includes iron foundry for 1955.

TAXES

Producers are granted a depletion allowance of 23 percent on domestic production and 15 percent on foreign production. Under the Defense Production Act the Accelerated Tax Amortization grants totaled $4,282,000. This program closed December 31, 1955.

TRANSPORTATION

Fluorspar is shipped by a variety of methods. Crude fluorspar may be hauled from the mines by truck to the mill or processing plant, and in this crude state it may be shipped by rail in open gondolas or hopper cars directly to the consuming industry. Finished fluorspar in the form of flotation concentrates may be shipped to consumers in 100-pound bags (four bags to a barrel) in boxcars, or in bulk in covered hopper cars. In the Illinois-Kentucky district several producers maintain loading facilities on the Ohio River for barge shipment to the Pittsburgh, Pa., area.

Handling and haulage techniques developed originally for shipping rocket fuels by trucks now enable chemical manufacturers in any part of the country to order liquid fluorine by the ton (*6*). One chemical manufacturer worked several years to develop a tank system having no moving parts or mechanical refrigeration. Having a fluorine capacity of 2½ tons, the system weighs 10 tons and consists of three horizontal cylindrical tanks one inside the other mounted on a semitrailer. As fluorine's normal boiling point is −306° F, the innermost tank containing the liquid fluorine is surrounded by a tank of liquid nitrogen (−320° F) and an outer tank filled with perlite or Santocel insulation and is then evacuated. Evaporation of the fluorine is prevented by the liquid nitrogen while nitrogen losses are effectively minimized by the efficient outer insulation.

RESEARCH

Fluorspar research in industry usually is directed toward improving mining and milling processes, changing the properties of finished concentrates, reducing the cost of these processes, and conducting reserve studies.

The Bureau of Mines has engaged in several projects involving research on the recovery of fluorspar and other fluorine compounds from phosphate rock and low-grade or complex fluorspar ores. Occasionally, fluorspar deposits are examined and studies made of mining methods and costs. Fundamental data on fluorine compounds are accumulated and published as a part of the Bureau's research on the thermodynamic properties of mineral materials.

OUTLOOK

Both the short- and long-term supply outlook for all grades of fluorspar required by domestic consumers are favorable, based on reserves in North America. Domestic production will probably continue to supply only about 20 to 35 percent of domestic consumption. Relatively low-cost and high-grade imported fluorspar will continue to restrict the movement of the domestic product, and the low prices of imported fluorspar will discourage expansion of the domestic industry.

Fluorine consumption is expected to increase as it has almost without interruption since the end of World War II. The growing aluminum, steel, and chemical industries will require more fluorine compounds. At the same time, it is likely that more cryolite will be reclaimed and reused at aluminum plants. Probably the greatest potentials for expansion lies in the relatively new and rapidly growing field of fluorine chemicals. The increasing use of the basic oxygen process in steelmaking expands the fluorspar market because this process requires about five times as much fluorspar per ton of steel as the basic open-hearth process. Fluorocarbon compounds, used for refrigerants, propellants, fluorinated plastics, and other fluorine compounds, can be expected to be used in increasing quanti-

ties in many applications. Fluorine is the active object of a wide variety of research in both organic and inorganic chemistry, and new uses are being discovered and developed.

The long-range trend in domestic fluorspar production is contingent upon the degree of competition from comparatively low-priced imported fluorspar, the price structure, and changes in tariff regulation, import restrictions, or market control. Production would also be affected by the solution of several technical problems involving the development of additional uses, reduced cost of distribution, and increased efficiency in exploration, development, mining, and milling.

In processing phosphate rock to make superphosphate fertilizers, gases are evolved which contain fluorine. Although plants in three States are now making or are capable of making synthetic cryolite from fluorine in processing phosphate rock, synthetic cryolite from this source is not expected to become a major factor in the fluorine market until far in the future when the price of fluorspar increases substantially. The development of an efficient, low-cost process for converting the silicofluoride to aluminum fluoride, synthetic cryolite, or other compounds suitable for industrial uses would change this outlook and increase the relative value of this source of fluorine. At present most phosphate producers find it more economic to neutralize the fluorine gases and discard the product than to recover the fluorine and attempt to sell it in a limited market.

The only free world source of natural cryolite is at Ivigtut, Greenland. This property has been operated for many years and its exhaustion is now within sight. Natural cryolite is comparatively expensive, so a synthetic cryolite industry has come into existence which uses fluorspar as a source of fluorine. The manufacture of cryolite from aluminum fluoride in the potline at aluminum plants, and additional reclaimed cryolite are expected to decrease the need for making this material separately from fluorspar.

PROBLEMS

The immediate problem of the domestic fluorspar-producing industry is to regain a portion of the domestic market that has been lost to imported material.

Defining the true strategic position of fluorspar also is a problem. Acid-grade and metallurgical-grade fluorspar are defined as strategic materials. Curtailment of domestic production has changed the Nation's supply picture and has provoked argument. One faction argues that domestic production should be maintained at all costs to keep mines in operation for an emergency, but the other attitude is that available nearby supplies (Mexico and Canada) are practically equivalent to a domestic supply.

Operators are often faced with the problem of whether to continue operating at a loss and maintaining resources or closing and running the risk of losing the mines. Although sizable resources are known, most domestic fluorspar deposits are underground, lower grade, and less accessible than many of the high-grade surface deposits in foreign areas which contribute major tonnages to the domestic market. In addition, a substantial tonnage of resources has been lost by flooding and caving-in of mines forced to shut down because of economic conditions. Other resources have been lost by the selective mining of high-grade areas.

A continuing long-term problem of the domestic fluorspar industry is the maintenance of a satisfactory reserve position.

The domestic fluorspar output is hampered by comparatively high costs of exploration, development, mining, beneficiation, and transportation. Production at some mines is hampered by excessive water.

Complexity of some of the domestic ores, stringent specifications on contaminants, and difficulties encountered in the utilization of low-grade ores are all major fluorspar problems.

Maintenance, classification, and interpretation of available statistical data for the guidance of Government and industry is a growing problem as the economic conditions change and complexities of fluorine production and consumption increase. Data are lacking from several areas of the statistical pattern, including recovery of fluorine from phosphate rock and secondary recovery as cryolite.

A quicker, more accurate field method of analyzing complex ores for fluorine is required, as present methods are slow, cumbersome, time consuming, and relatively expensive.

GALLIUM

By Donald E. Eilertsen [1]

GALLIUM, discovered in 1875, was not produced commercially in the United States until 1943. The element is notable because it melts at 30° C, or about 86° F. The metal is recovered commercially as a byproduct in the extraction of alumina from bauxite and zinc from sphalerite; production is small. Gallium's largest use and largest interest in research in recent years have been as a semiconductor. Other uses are in selenium rectifiers, in dental alloys, and as a sealant for glass joints in laboratory equipment. The resource of gallium in bauxite and zinc reserves is very large.

BACKGROUND

Gallium was discovered in 1875 and first produced in the United States in 1915 from metallic residues obtained in redistillation of zinc spelter during the extraction of zinc from zinc mineral concentrate. Several thousand grams of gallium were produced commercially from domestic ores during 1943–45; production was almost 200 pounds in 1948. Three firms produced gallium for a number of years, but in recent years there have been only two.

ORGANIZATION AND GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

The Aluminum Company of America, Bauxite, Ark., produces gallium metal, and The Eagle-Picher Co., at its Miami plant near Quapaw, Okla., produces gallium metal and compounds. Gallium is a minor byproduct at both companies mineral processing plants.

DEFINITION OF TERMS, GRADES, AND SPECIFICATIONS

Gallium (Ga), silvery white in high-purity form, has atomic number, 31; atomic weight, 69.72; melting point, 29.78° C; boiling point, 2,403° C; and densities as follows: 5.904 grams per cubic centimeter (g/cm^3) at 29.6° C (solid), 6.095 g/cm^3 at 29.8° C (liquid), and 5.445 g/cm^3 at 1,100° C. Some of its other properties follows: Expansion upon solidifying, 3.2 percent; specific heat from 12.5° C to 200° C, 0.095 calorie per gram per degree centrigrade; and latent heat of fusion, 19.16 calories per gram (*1*).[2] Liquid gallium aggressively attacks solid metals, especially at high temperatures, and is extremely difficult to contain. Gallium and its compounds are generally nontoxic.

Gallium purities are sometimes expressed in terms of nines; that is, 99.999 percent pure gallium is 5–9s purity.

Gallium metal and some of its compounds are available in very high purities such as 99.99999 percent purity gallium (7–9s), and 99.9999 purity gallium sesquioxide (6–9s.)

TECHNOLOGY

Mineralogy and Occurrence

The earth's crust is estimated to contain 15 parts per million of gallium, compared to 16 parts per million of lead. Gallite, $CuGaS_2$, from South-West Africa is the only known mineral that contains gallium as an essential constitutent, but the quantity of gallite seems to be small (*3*). Numerous minerals contain gallium as an impurity. Almost all highly aluminous rocks and minerals contain detectable gallium. It has been identified in many minerals; among them are adamite, alunite, amazonite, bauxite, beryl, coal, diaspore, enargite, gahnite, germanite, hopeite, lepidolite, margarite, microcline, muscovite, parahopeite, phlogopite, sphalerite, spodumene, and tennantite. Gallium is recovered commercially as a byproduct in the United States from impure bauxite and impure sphalerite. The gallium content of sphalerite from the Tri-State area

[1] Commodity specialist.

[2] Italicized numbers in parentheses refer to items in the list of references at the end of this chapter.

ranges from 0.001 to 0.02 percent, and averages about 0.005 percent. Bauxites are known to contain up to 0.01 percent gallium.

Germanite, a complex sulfide of copper, iron, and germanium found in East Germany and South-West Africa, has been known to contain up to 1.85 percent gallium.

Metallurgy

In the Bayer process for extraction of alumina (Al_2O_3), bauxite is digested in caustic solution and the major impurities, ferric oxide and silicon dioxide, are separated from the alumina. The alumina subsequently is precipitated and the spent caustic solution containing gallia (Ga_2O_3) is recycled to treat more bauxite. Owing to continuous reuse of the caustic solution, the gallia builds up to an equilibrium concentration and additional gallia then precipitates along with alumina. Gallium is recovered from the caustic solution by chemical and electrolytic procedures (*1*).

In zinc extraction operations, gallium might appear in the following products:

Residues from primary retorts, spelter from primary distillation, residues from redistillation of primary spelter, residues from zinc oxide furnaces and Waelz kilns, purification precipitates of zinc sulfate solutions at electrolytic plants, and residual zinc sulfate solution at lithopone plants.

The Eagle-Picher Co. separated gallium from the iron residue resulting from the production of zinc sulfate solution from sphalerite. Gallium hydroxide is separated from iron hydroxide, is converted to trichloride, and is purified by ether partition. The purified gallium trichloride is converted to sodium gallate and is electrolyzed, using a copper rod cathode and platinum anode. The cell temperature is kept well above 29.75° C, the melting point of gallium. Electrolysis is at 5.5 volts and 0.5 ampere per square centimeter of anode and 0.33 ampere per square centimeter of cathode. Liquid gallium collects on the tip of the cathode and drains into a poreclain crucible.

The crude liquid gallium is washed several times alternately with distilled water, dilute hydrochloric acid, and dilute nitric acid. A dark colored dross formed during the nitric wash is removed by skimming. Chemical cleaning of the gallium is complete when no dross forms during the nitric wash and when the gallium forms a mirror-like pool after the hydrochloric treatment. The liquid metal is cooled below its melting point, is seeded with crystalline gallium, and gallium crystals are removed as they form. They are dried, packed in pliofilm or rubber bags, and kept at about 15° C (*6*).

USES (*1*)

The largest use at present by far for gallium and some of its compounds is in semiconductors and in research and development of electronic devices. The availability of extremely high-purity gallium and some of its compounds has led to the production of semiconductors with properties closely approaching those predicted from theory. Some of the new developments include use of gallium as a dopant for semiconductors, and use of gallium arsenide in high-temperature and high-frequency transistors; tunnel diodes which have applications in switching and FM transmitter circuits, replacement for phase-locked ocillators, and amplifiers; solar cells for solar batteries; and in research concerning use of lasers.

Other applications include the uses of gallium oxide for vapor-doping of other semiconductor material; of the oxide and halides for epitaxial growth of gallium arsenide and gallium phosphide; and of gallium ammonium chloride in plating baths for electrodepositing gallium onto whisker wires for leads of transistors.

Gallium metal is used in certain selenium rectifiers, as sealant for glass joints in mass spectrometers and other laboratory equipment, as backing for mirrors, and for special thermometers.

Gallium has promising application in alloys. For example, a certain dental alloy can support the pressure of a ton on a 0.03-square-inch area, a compressive pressure of 33 tons per square inch. Gold-platinum-indium alloys are being used for dental restorations. Two other dental alloys are being reevaluated, one containing 14 percent gallium and 86 percent of a silver alloy, and the other alloy containing 36 percent gallium, 62.1 percent nickel, and 1.88 percent silicon. Certain vapor-arc lamps contain gallium-cadmium-zinc alloys. Other gallium alloys are used as low-resistance contact electrodes for bonding wire and thermocouples to ferrites and semiconductors.

ALTERNATE AND SUBSTITUTE MATERIALS

Substitutes are known for almost all of gallium's commercial applications but the performance may not be as good as for gallium. In the field of semiconductors germanium, silicon, indium antimonide, and indium arsenide are some of the competitors of gallium arsenide. Although gallium can sometimes be substituted

for other metals, cheaper metals usually are used instead of gallium.

RESERVES

Rough estimates of the gallium resources in bauxite and zinc reserves are obtainable by assuming that the bauxite resource contains 0.004 percent gallium and zinc resources contain 0.006 percent gallium. The resource of gallium from these sources, in short tons, is as follows:

	United States	World
Gallium in bauxite reserves	2,000	230,400
Gallium in zinc reserves	720	5,460
Total	2,720	235,860

SOURCES OF STATISTICAL INFORMATION

Data on domestic production and consumption of gallium are obtained by the Bureau of Mines through industry canvasses; however, company confidential data are not publicized.

Data on imports of gallium metal are obtained by the Bureau of Mines through the U.S. Department of Commerce. No data are available on imports of gallium compounds and exports of gallium metal and its compounds.

PRODUCTION, CONSUMPTION, AND TRADE

Estimates indicate that gallium output could be increased substantially if needed. Aluminum Company of America and The Eagle-Picher Co. have been the only gallium producers in the United States in recent years. In 1946–63, gallium was produced by The Aluminum Company of America during 1947–48, 1950–51, 1953–63; and by The Eagle-Picher Co. during 1946–48, and 1957–63. Record output of domestic gallium occurred in 1961, while record shipment of gallium occurred in 1963.

Gallium is produced in approximately six foreign countries. Figures on imports of gallium have been available since September 1, 1963, when a new system of reporting began. Imports of unwrought gallium and waste and scrap for consumption during September–December 1963 were 1 pound, valued at $486, from France; 16 pounds, valued at $7,000, from Switzerland; and 1 pound valued at $606, from the United Kingdom.

Tentative general imports of these materials during 1964 were 5 pounds, valued at $1,037, from France; 321 pounds, valued at $64,389, from Switzerland; 55 pounds, valued at $9,842, from the United Kingdom; 14 pounds, valued at $3,056, from West Germany; 22 pounds, valued at $4,943, from Hungary; and a quantity to be confirmed, valued at $3,846, from Mexico.

Duty of 50 cents per long ton on bauxite has been suspended. Sphalerite concentrate is dutiable at 0.67 cent per pound of zinc content. Gallium metal is dutiable at 10.5 percent ad valorem.

STRATEGIC CONSIDERATIONS

The United States is self-sufficient in gallium because gallium output could be greatly increased if needed, but perhaps at higher prices. Gallium is not on the Government's list of strategic and critical materials for stockpiling.

PRICES

TABLE 1.—*Market prices of gallium from bauxite sources in 1963–64*

[Per gram]

Quantity	99.99 percent	99.999 percent	99.9999 percent
Up to 999 grams	$1.40	$1.50	$1.70
1,000 to 4,999 grams	1.20	1.30	1.50
5,000 to 24,999 grams	1.10	1.15	1.35
Over 25,000 grams	.95	1.00	1.20

RESEARCH

Gallium semiconductors materials have been the subject of intense research and development in recent years.

The bibliography of gallium is extensive (*2, 4–5*).

Currently, the Bureau of Mines is conducting studies on gallium alloying and extraction of germanium and gallium from coal-fly ashes and flue dusts.

OUTLOOK

Gallium, abundant as lead in in the earth's crust, is found in nature only as a minor constituent in various minerals, the commercial source being certain bauxites and sphalerites. Producers could increase gallium production fourfold or fivefold with equipment now in use, and additional capacity could be built easily if needed.

Consumption seems likely to continue at small quantities annually, the largest use being in intermetallic compounds for semiconductor applications and in research in this field. Conventional uses will continue for gallium in certain selenium rectifiers, as a material for sealing glass joints and valves in laboratory vacuum equipment, for backing mirrors, for special thermometers, and for low-melting alloys used in dentistry. Significantly greater demand for gallium is not likely unless some unexpected research development occurs, such as in extensive semiconductor application. Currently gallium arsenide shows promise for application in high-temperature and high-frequency transistors, lasers, and tunnel diodes.

PROBLEMS

The principal gallium problem is the lack of demand. Despite its unusual properties only a small fraction of the potential output from bauxite and sphalerite sources has been achieved.

Problems associated with gallium extend from detection through refinement and development of uses. Despite the abundance of gallium its occurrence in nature is irregular. The prospector finds it difficult to detect gallium in the field. Source materials are so low in gallium that costly multistage extraction techniques have to be employed to enable good recovery. The resultant high price restricts demand and serves as a barrier in the development of new applications.

There is insufficient knowledge of the physical and chemical properties of gallium metal and its alloys and compounds, to stimulate their application. Gallium's corrosive attack on other metals at elevated temperatures leads to contamination from vessels holding it during alloying, thus adversely influencing the properties of gallium-bearing intermetallic semiconductors produced. Gallium is so reactive chemically at high temperatures that use of the liquid metal in thermal transfer applications such as in nuclear energy would require special metal container materials.

GARNET

By Paul M. Ambrose [1]

GARNET is a semiprecious gem; however, because of an unusual combination of properties, its main usefulness is as an industrial abrasive. It is used extensively in glass grinding, metal lapping, and wood, leather, and plastic sanding where close quality control is required.

Since 1878 garnet has been used extensively in the United States in manufacturing abrasive papers and cloths. In recent years it has been used as a sandblasting abrasive; for grinding plate glass, optical lenses, and other glass surfaces; and for metal polishing. Eleven abrasive manufacturing companies are producing garnet papers and cloths in the United States.

Peak garnet output in the United States was reached in 1963, when 14,626 short tons was sold. The Barton mine in New York is the largest garnet producer in the world. It has been operated continuously since 1878 and has a large ore reserve. Production from alluvial garnet deposits in Idaho supplies the Pacific Coast States with a sandblasting material. Other garnet output is mainly a byproduct from the milling of other materials.

In 1963 the reported value ranged from $25 per ton for garnet produced in Idaho to $140 per ton for New York garnet.

The currently producing garnet mines are able to satisfy market requirements, and exhaustion of the major sources of supply is not in prospect.

The use of garnet is expected to increase in proportion to the growth of the abrasive industry. The overall problem of the abrasive industry is the lack of definitive criteria for comparing the merits of various abrasive materials. The principal problems of the established producers of garnet are maintaining and increasing sales in the face of active competition from other abrasives.

BACKGROUND

This chapter deals solely with industrial garnet. Gem quality garnet is included in the Gem Stones chapter.

SIZE, ORGANIZATION, AND GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

Abrasive garnet production began in the United States in 1878 at the site of the present Barton mine, which since has been owned continuously by the same family. In 1878 less than 100 tons was mined, and this output was used in coated abrasives (papers and cloths). With minor fluctuations, industrial garnet sales increased to a peak of 14,626 tons in 1963. Since 1951 the annual value of sales has averaged more than $1 million.

Barton Mines Corp., the largest domestic producer, operates the Barton open-pit mine and mill near North Creek, Warren County, N.Y. The output is sold directly to consumers, chiefly in the Northeastern States, as graded material. About 60 percent of the output is used to manufacture coated abrasives; the remainder is used for glass grinding and other miscellaneous uses. The Idaho Garnet Abrasive Co., and Emerald Creek Garnet Milling Co., Fernwood, Idaho, mine an alluvial garnet deposit by dragline excavator. The concentrate is sold on the Pacific coast for sandblasting and spark-plug cleaning. Porter Brothers Corp. of Boise, Idaho, recovers garnet as a byproduct from dredging operations in Valley County, Idaho. Small quantities of low-value garnet are produced as a byproduct of wollastonite mining by Cabot Minerals Division, Cabot Corporation, Willsboro, N.Y.

[1] Commodity specialist.

Garnet-coated abrasive papers and cloths are produced by 11 manufacturers at plants distributed as follows: New York, three; Connecticut, Massachusetts, and Michigan, two each; and Minnesota, Ohio, and Tennessee, one each.

Although garnet is found throughout the world and is mined in many countries as a gem material, its production for industrial use is recorded only in the United States, Argentina, Malagasy Republic, Spain, Tanganyika, Republic of South Africa, and the U.S.S.R. The deposits in the U.S.S.R. are similar to the Barton Mines deposit in the United States, and the mill design was based on a former Barton Mines flow sheet.

DEFINITION OF TERMS, GRADES, AND SPECIFICATIONS

Garnet is the name of a group of iron-aluminum silicate minerals having similar physical properties and crystal form. Of the many varieties known, almandite ($FeO \cdot Al_2O_3 \cdot SiO_2$) is the most important to industry. Crude garnet ore or concentrate is no longer marketed. Consumers purchase material crushed, ground, and graded to various screen and micron sizes depending upon their needs. The distinctions between grain sizes and powder sizes is arbitrary because there is no exact line which separates grain and powder.

Government specifications for garnet coated abrasives are included in Federal Specifications: P–p–121a June 17, 1953; p–p–00121b (GSA–FSS) interim; and P–P–126a(1), May 16, 1960.

TECHNOLOGY

Almandite, the most important type of garnet industrially, has a hardness of 7.5 to 8, a specific gravity of 4, a melting point of 1,315° C, a color of various shades of red, and a chemical composition of $FeO \cdot Al_2O_3 \cdot SiO_2$; it crystallizes in the cubic system. The sharp fracture and toughness of almandite make it desirable for certain abrasive uses.

At the Barton mine the garnet occurs in a metamorphosed igneous rock, the ore body being 150 to 200 feet wide with outcroppings that can be traced more than 4,000 feet (*6*).[2] The garnet content of the part of the ore body being mined ranges from 12 to 15 percent. Single crystals 1 foot in diameter are common. The garnet has two sets of jointing planes at approximately 90°, which control the shape of the crushed particles. It is believed that the exceptional abrasive quality of garnet from the Barton mine can be attributed to this unusual feature. Garnet in the weathered zone, which extended to a depth of approximately 15 feet, was easily hand-sorted, and it was not until mining of the unweathered rock began that a concentration plant became necessary.

The mine consists of a series of opencut benches. The broken ore is loaded into trucks by power shovels for transportation to the mill, about one-quarter of a mile away.

Separation of the gangue minerals from the garnet is achieved by a combination of methods including jigging, tabling, flotation, magnetic separation, water sedimentation, and air separation.

The first step towards separation begins with crushing followed by a series of grinding steps until each particle of garnet is free of its matrix rock or various minerals which had been intruded or encased in the garnet crystals. Liberation is completed only after garnet particles have been ground to grain and powder sizes that can be marketed. After liberation has been effected in each size range, a close grading is necessary before separation. This sizing is done by screening or water sedimentation. In some cases the same process will perform sizing and separation but in most cases consecutive processes are required. In all cases liberation, separation, and sizing are necessary to obtain marketable garnet.

The distinction between grain sizes and powder sizes is arbitrary because there is no exact line which separate grain from powder. Each results from the same grinding or regrinding which precedes the sequence of separation-grading-separation. Each requires both liberation and separation; the complicating factor is that different size ranges require different types of processes or combinations of processes. Unfortunately no process of grinding can control particle size distribution.

Final grade specifications, some of which are government applied, some industry applied, and some determined by individual customer requirements, are so close and exacting that in any given range of sizes only certain segments of the range can be extracted and made into marketable grades. The in-between sizes which fall outside of the grades at either end must be reground into still finer material. This process is repeated as often as necessary until the particles eventually fall within a grade specification which is marketable. In many cases good milling technique has dictated that final grading be achieved before final separation. Garnet which undergoes regrinding is either garnet which has not been entirely liberated or garnet in "in between" or unmarketable particle sizes. Thus a continuous series of grinding and processing steps are required despite the fact each

[2] Italicized numbers in parentheses refer to items in the list of references at the end of this chapter.

regrinding as well as the original grinding produces in varying amounts the entire range of grain and powder sizes, some of which are uncontrollably reduced beyond that size for which any market exists.

During the entire milling operation there are two basic objectives; purifying the concentrate and sizing the garnet into marketable grades. Garnet processing includes packing because in this final operation great care and control must be exercised to prevent a mixture of grades or a single particle of contamination from entering the container. A prime objective also is to capture the maximum portion of the garnet in the ore.

The abrasive qualities of garnet are improved considerably by roasting for several hours at 800° to 900° C. This has the effect of increasing its toughness and abrasive properties. Temperatures higher than 1,000° C have a detrimental effect on the final product.

Extensive alluvial deposits of almandite garnet occur on Emerald Creek, Benewah County, Idaho. An overburden of 3 to 8 feet is stripped to expose gravel containing as much as 20 percent garnet. Mining is done with a dragline dredge. The material passes to a trommel and then is treated in jigs and on concentrating tables. The maximum garnet grain size is three-sixteenth inch. The garnet concentrate is dried, crushed, and screened to produce the different sizes required by industry. The crushed material is a better abrasive than the uncrushed because sharper cutting edges are formed.

A garnet concentrate is obtained as a byproduct of wollastonite mining at Willsboro, N.Y. It has been produced as a byproduct of rutile mining near Melbourne, Fla., and from the reworking of mill tailings at Bishop, Calif. Only a limited market has been developed for this byproduct garnet.

USES

The major industrial use for garnet since before 1880 has been as an abrasive material in such applications as optical lens grinding, plate glass grinding, lapping of semiconductor materials and metals where a high quality, scratch-free surface is required. It is also used in nonskid floor paint. Coated papers and cloths are used for finishing wood, leather, hard rubber, felt, and plastics. Spark plug cleaning is a minor use.

The aluminum, aircraft, and shipbuilding industries in California and the Pacific Northwest have found alluvial garnet principally from Idaho to be a good material for sandblasting.

ALTERNATE MATERIALS

Garnet has achieved a unique place in the coated-abrasive field between low-cost quartz and high-cost artificial abrasives (silicon carbide and aluminum oxide). Garnet is preferred over quartz, as it is more efficient and its fracture imparts a more desirable finish to products made of wood, leather, hard rubber, felt, and plastics. Garnet abrasives cannot compete with artificial abrasives for most metalworking applications because of its friable nature and lower hardness rating. If garnet were not available, quartz and artificial abrasives could be used in its place.

RESERVES

New York has the largest known garnet reserve in the United States, the supply being adequate for the foreseeable future. For many years the reserve has been developed through exploration at a rate at least equal to consumption. The quantity of garnet-bearing gravel at Emerald Creek, Idaho, is reported to be large. No quantitative data are available on garnet resources in the United States or other countries.

SOURCES OF STATISTICAL INFORMATION

The Bureau of Mines annually canvasses all known producers of garnet in the United States. The only source of information on foreign garnet production is its infrequent mention in Department of State dispatches, annual publications of the Colonial Geological Survey (United Kingdom), and the technical press. Exports are included with natural abrasives not elsewhere classified. Production of garnet paper and cloth is reported monthly by the Coated Abrasive Manufacturers' Institute.

PRODUCTION, CONSUMPTION, AND TRADE

Table 1 gives the tonnage and mine value of garnet mined in recent years in the United States. Output of finished product is virtually the same as sales.

TABLE 1.—*Abrasive garnet sold or used by producers in the United States*

Year	Short tons	Value (thousands)	Year	Short tons	Value (thousands)
1954–58 (average)	11,582	$1,037	1961	12,057	$1,036
1959	14,568	1,211	1962	14,166	1,172
1960	10,522	986	1963	14,626	1,412

In addition to New York and Idaho, domestic garnet production has been reported in the past from California, Connecticut, Florida, New Hampshire, North Carolina, and Pennsylvania. (*3*, *6*). It has been recovered from mill tailings near Bishop, Calif. Most of the world's garnet is produced in the United States. It is estimated that U.S.S.R. produces about 2,000 tons a year and that the combined production of Argentina, Australia, Malagasy Republic, Spain, Tanganyika, and Republic of South Africa does not exceed 1,000 tons annually.

Garnet is exported as graded material, but quantitative data are not available. No imports of industrial garnet were reported in 1963.

PRICES

The reported value of garnet ore ranges from $25 per ton for Idaho material to $140 for New York material. Finished New York abrasive garnet ranges from 12¾ cents per pound for powder in carload lots to 53 cents per pound for micron-size powder in retail lots. In many instances closely sized grain is more expensive than some powder. For example, a certain grade of powder, necessarily produced in milling, may sell for about 13 cents per pound and 240 to 280 mesh grain may be 22½ cents per pound.

TAXES

No special taxes are imposed on the garnet industry. Producers are granted a depletion allowance of 15 percent on domestic and foreign production.

RESEARCH

Research is conducted by Barton Mines Corp., especially in developing uses for finely ground garnet, which brings a premium price, and on better heat-treatment methods to improve the abrasive properties of garnet.

OUTLOOK

The currently producing garnet mines of the United States can fulfill foreseeable domestic market requirements and export demand at present market prices for this abrasive material. There is no prospect for the major domestic sources of supply to become exhausted. The good quality garnet in the extensive ore reserve at the Barton Mine in New York indicates an ample supply. The Idaho alluvial deposits contain a large tonnage of garnet which is available for sandblasting and similar uses in the Northwestern States. Byproduct garnet is accumulating from the milling of wollastonite, ilmenite, and other minerals at a rate faster than a market can be found for it, even at reduced prices.

New mining and milling methods may reduce the cost so that garnet can enter the field now held by lower-priced abrasives. Improved heat-treatment methods, combined with lower prices and more intensive sales effort, may offer garnet a chance to compete favorably with artificial abrasives and develop a wider market.

In the past 20 years the use of garnet increased about in equal proportion to the expansion of the entire abrasive industry. This trend seems likely to continue. The use of finely ground garnet and garnet powders in grinding and polishing compounds, nonskid paints and floor surfaces, spark-plug cleaning, and as a facing for building bricks has increased due to research and sales effort. While adding but little to the total tonnage of garnet sold, the higher prices that some special garnet products command increases materially its sales value.

Imported garnet does not compete with the domestic material, either in quality or price. Export of domestic garnet probably will continue, especially where a carefully processed material of good abrasive quality is needed.

A more intensive sales effort on the part of other abrasives may be the only action that would prevent the continued and possibly increased demand for garnet.

PROBLEMS

Garnet shares the overall problem of the abrasive industry in that it lacks a definitive and acceptable method of evaluating its abrasive qualities compared with other minerals and materials. Hardness, per se, does not assure that a material is a good abrasive. Other factors, including type of fracture, crystal form, friability, and ability to withstand heating also in part determine the abrasive value of a substance. Consequently, personal preferences and price often dictate the choice of abrasives.

The principal problems of the established garnet abrasive industry are maintenance of and means of increasing sales in the face of active competition from other abrasives. Numerous mineral operations are potential sources of byproduct garnet, but their development is usually limited as the market is adequately supplied with good-quality material from established sources. Local markets for abrasive used in nonskid pavements and paints might be developed near the sources of byproduct garnet.

GEM STONES

By Benjamin Petkof [1]

GEM MATERIALS must have three principal qualities—beauty, durability, and rarity.

Gem stones are formed primarily by crystallization from aqueous solutions, crystallization from magmas, and metamorphism. Most economic deposits are in pegmatites, kimberlite pipes and dikes, and placers.

At least one variety of gem stone occurs in each State. More than 60 gem minerals, nearly all semiprecious, have been produced domestically, mostly from the Western States. In 1963 the U.S. gem stone production was valued at more than $1.4 million. Imports, mainly diamond, amounted to nearly $256 million. A prime feature of domestic production was the activity of amateur collectors, who collected, cut, and polished gems and manufactured jewelry as a hobby.

Virtually all gem stones are used for decorative purposes, mainly in jewelry but also for statuettes, vases, and other art objects, and for exhibit in private and public collections.

Materials used as substitutes for gem stones include plastics, glass, metals, and wood. Some synthetic gem stones compete with natural gems.

The price of a finished gem stone is determined primarily by its beauty, durability, rarity, freedom from defects, and perfection of cutting.

A chief problem of the domestic gem stone industry is lack of deposits of high-quality gem stones and low productivity in cutting and polishing compared with other countries.

BACKGROUND

SIZE, ORGANIZATION, AND GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY (*8, 10, 28*)[2]

Only a few commercial mining firms are active in domestic gem stone production.

For the most part, production lies in the hands of numerous dedicated hobbyists and members of gem societies and clubs who spend their time and effort searching out interesting mineral deposits. Some collect only for the sake of mineral specimens; others cut and polish their finds into various crystal shapes and forms. Much of the trading consists of barter or exchange of specimens between collectors. Because of this situation, it is not possible to measure reliably the commercial magnitude of mining, processing, and trading of domestic gem stone.

More than 60 gem minerals, mostly semiprecious, have been produced commercially from domestic sources, and at least one variety of gem stone occurs in each State. About 87 percent of the total U.S. gem production, in order of decreasing value, comes from Oregon, California, Texas, Arizona, Nevada, Wyoming, Utah, Washington, Colorado, and Montana. The remaining production comes principally from other localities in the Rocky and Appalachian Mountains systems. Table 1 lists the principal gemstone localities in the United States.

World gem-diamond production comes mainly from Africa and South America. The principal producing countries are in Africa: Republic of South Africa, South-West Africa, Ghana, and Sierra Leone; in South America: Brazil, British Guiana, and Venezuela.

Foreign localities where major gem stone deposits, other than diamond, occur are: Australia (opal, beryl), Brazil (topaz, ruby, sapphire, beryl, agate), Burma (topaz, ruby, sapphire, beryl, jade), Ceylon (topaz, ruby, sapphire, beryl), Malagasy Republic (sapphire, tourmaline, rose quartz, beryl), and Mexico (topaz, opal, agate).

Such precious stones as diamond and emerald are imported in cut and uncut condition and

[1] Commodity specialist.
[2] Italicized numbers in parentheses refer to items in the list of references at the end of this chapter.

distributed through jobbers and dealers. Cutting, polishing, and mounting is done by commercial lapidaries and jewelers in large industrial centers such as New York City. During 1963, imports of precious and semiprecious stones were valued at $256 million. About 2.8 million carats of cut and uncut diamonds were imported and represented about 88 percent of total imports by value.

Because of high labor costs, limited quantities of semiprecious stones are actually cut and polished in the United States. Most of this material is worked in nations where the cost of hand labor remains relatively low.

The Diamond Trading Co., Ltd., and the Industrial Distributors Ltd. market in excess of 90 percent of both gem and industrial diamond. These groups sell exclusively for the Diamond Corp. Ltd., which is under the control of DeBeers Consolidated Mines Ltd. and Consolidated Diamonds of South-West Africa. The Diamond Corp., through outright purchase or agreement, controls the sale and production of almost all large producers.

State and county	*Gem materials*
Alaska:[1]	
Cook Inlet-Susitna	Soapstone.
Northwestern Alaska	Jade.
Southeastern Alaska	Agate, garnet, jade.
Arizona:	
Apache	Agate, obsidian, peridot, petrified wood.
Cochise	Agate, amethyst, azurite, malachite, shattuckite.
Coconino	Agate, obsidian, petrified wood.
Gila	Agate, amethyst, azurite, bloodstone, carnelian, chalcedony, chrysocolla, epidote, garnet, hypersthene, obsidian, opal, peridot, pertified wood, serpentine, turquoise.
Graham	Agate, azurite, banded agate, chalcedony, malachite, obsidian, onyx, opal, pertified wood, turquoise.
Greenlee	Agate, amethyst, azurite, chalcedony, chrysocolla, garnet, jasper, malachite, obsidian, onyx, opal, petrified wood, rose quartz, shattuckite, turquoise, variscite.
Maricopa	Agate, amethyst, chalcedony, fire agate, jasper, marble, onyx, opal, petrified wood, plume agate.
Mohave	Agate, chalcedony, chalk turquoise, jasper, pertified wood.
Navajo	Garnet, petrified wood.
Pima	Azurite, chalcedony, malachite, obsidian, shattuckite.
Pinal	Chalcedony, chrysocolla, obsidian, peridot.
Yavapai	Agate, carnelian, chalcedony, chrysocolla, chrysoprase, jade, jasper, moonstone, obsidian, onyx, petrified wood, quartz crystal.
Yuma	Agate, chalcedony, garnet, jasper, obsidian, petrified wood, quartz crystal, rhyolite, turquoise.
Arkansas:	
Garland	Novaculite, quartz crystal.
Hot Spring	Quartz crystal, smoky quartz.
Montgomery	Quartz crystal.
Pike	Diamond.
California:	
Alameda	Agate.
Alpine	Do.
Amador	Rhodonite.
Calaveras	Agate, chalcedony, chrysoprase, petrified wood, quartz crystal.
Colusa	Travertine.
Contra Costa	Agate.
Del Norte	Agate, jasper, petrified wood.
El Dorado	Agate, garnet, idocrase, jasper, nephrite, petrified wood, vesuvianite.
Fresno	Chert, jasper, petrified wood, smoky quartz.
Humboldt	Agate, jade, jasper, petrified wood.
Imperial	Agate, andalusite, chalcedony, dumortierite, garnet, jasper, kyanite, opal, petrified palm root, petrified wood.
Inyo	Agate, amethyst, bloodstone, epidote, garnet, geode, jasper, obsidian, onyx, opal, quartz crystal, turquoise.
Kern	Actinolite, agate, colemanite crystal, jade, jasper, morrisonite, petrified wood, quartz crystal, rhodonite, rose quartz.
Lake	Jasper, onyx, quartz crystal.
Los Angeles	Agate, chalcedony, jasper, rhodonite.
Madera	Chiastolites.
Marin	Agate, jade, petrified whalebone.
Mariposa	Quartz crystal.
Mendocino	Agate, jade, jasper, opal, quartz.

[1] Alaska has no county designation.

Wilkes	Agate.
Yancey	Emerald, feldspar gems.

TABLE 1.—*Partial list of localities in the United States where gem materials have been reported found in 1953–63*—Continued

State and county	*Gem materials*
North Dakota:	
Adams	Petrified wood.
Billings	Do.
McLean	Do.
Morton	Do.
Stark	Chalcedony, jasper, quartz crystal.
Ohio:	
Coshocton	Flint, selenite crystal.
Franklin	Petrified wood.
Gallia	Do.
Licking	Flint, jasper.
Lucas	Fossils.
Montgomery	Agate, gem granite.
Muskingum	Jasper.
Ottawa	Celestite, fluorite.
Wood	Barite, calcite.
Oklahoma:	
Canadian	Agate, jasper, petrified wood.
Comanche	Zircon.
Dewey	Agate, chalcedony, jadite, jasper, petrified wood.
Greer	Alabaster.
Jackson	Quartz.
Major	Agate, jasper, petrified wood.
Ottawa	Sphalerite.
Pushmataha	Green quartz.
Oregon:	
Baker	Agate, jasper, petrified wood.
Benton	Agate.
Coos	Fossil wood.
Crook	Agate, carnelian, geode, moss agate.
Curry	Jade.
Deschutes	Agate, carnelian, geode, jasper, moss agate.
Douglas	Agate.
Grant	Agate, petrified wood.
Harney	Agate, obsidian.
Jackson	Agate, bloodstone, jasper, petrified wood, rhodonite.
Jefferson	Agate, amethyst, geode, opal.
Lake	Geode, obsidian.
Lane	Agate, petrified wood.
Lincoln	Agate, agatized coral, bloodstone, jasper, petrified wood, sagenite, sardonyx.
Linn	Agate.
Malheur	Agate, geode, jasper, petrified wood.
Morrow	Agate, geode.
Polk	Agate, jasper, petrified wood.
Union	Agate.
Wallowa	Do.
Wasco	Agate, amethyst, bloodstone, chalcedony, geode, jade, jasper, opal, quartz, sagenite.
Wheeler	Agate.
Pennsylvania:	
Adams	Cuprite.
Bedford	Calcite, quartz, spar.
Berks	Calcite, epidote, feldspar, garnet, hematite, kyanite, magnetite, quartz crystal, unakite, zeolite.
Bucks	Galena, sphalerite.
Carbon	Autunite, carnotite.
Chester	Anglesite, azurite, feldspar, garnet, goethite, hornblend, kyanite, magnetite, malachite, martite, phlogopite, pyromorphite, pyrite, pyrrhotite, quartz, quartz crystal, sphalerite, sulfur, stibnite, wulfenite.
Cumberland	Phosphorite.
Delaware	Actinolite, apatite crystal, deweylite, feldspar, garnet.
Lancaster	Actinolite, aragonite, calcite, chalcedony, chromite, dolomite, hematite, malachite, marcasite, quartz crystal, pyrite, serpentine.
Lebanon	Anthophyllite, apophylite, biotite, garnet, hematite, magnetite, serpentine.
Lehigh	Calamine, corundum, goethite, greenockite, jasper, quartz crystal, sphalerite.
Monroe	Quartz crystal.
Montgomery	Calcite, galena, lead and copper minerals, natrolite, quartz crystal, sphalerite, stibnite, zeolite.
Northampton	Calcite, graphite, gummite, limonite, serpentine, talc, uraninite.
Perry	Travertine.

TABLE 1.—*Partial list of localities in the United States where gem materials have been reported found in 1953–63*—Continued

State and county	*Gem materials*
Pennsylvania—Continued	
Schuylkill	Chlorite, galena, pyrite, quartz crystal, siderite, sphalerite.
Somerset	Quartz.
Westmoreland	Petrified wood, quartz.
York	Limonite, pyrite.
Rhode Island: Providence	Amethyst, beryl, fluorite, quartz crystal.
South Carolina:	
Anderson	Tourmaline.
Chesterfield	Topaz.
Florence	Petrified wood.
South Dakota:	
Custer	Agate, amblygonite, beryl, chalcedony, feldspar, garnet, jade, jasper, lepidolite, mica, petrified wood, quartz crystal, rose quartz, sillimanite, tourmaline.
Fall River	Agate, chalcedony, jasper, petrified wood, vanadanite.
Harding	Agate, petrified wood.
Lawrence	Garnet, rose quartz.
Meade	Gastroliths, geode, petrified wood, selenite.
Pennington	Agate, apatite, beryl, chalcedony, feldspar, galena, garnet, jasper, lepidolite, petrified wood, rose quartz, staurolite, tourmaline.
Shannon	Agate, jasper, petrified wood.
Tennessee:	
Bedford	Agate.
Carter	Unakite.
Coffee	Agate.
Texas:	
Brewster	Agate, amethyst, carnelian, chalcedony, citrine, fire opal, jasper, labradorite, moonstone, novaculite, petrified wood, quartz.
Burnet	Garnet, topaz.
Culberson	Agate.
De Witt	Agate, jasper, petrified wood.
Duval	Do.
El Paso	Agate.
Fayette	Petrified wood.
Gillespie	Amythest, garnet, petrified wood, topaz.
Gonzales	Petrified wood.
Hidalgo	Agate.
Hudspeth	Do.
Jeff Davis	Adularia, agate, amethyst, carnelian, chalcedony, citrine, jasper, moonstone, opal, petrified wood, quartz crystal.
Lee	Petrified wood.
Live Oak	Agate, petrified wood.
Llano	Amethyst, garnet, quartz crystal, topaz, tourmaline.
McMullen	Petrified wood.
Mason	Amazonite, cassiterite, fluorite, quartz, topaz.
Pecos	Agate.
Potter	Petrified wood.
Presidio	Agate, amethyst, carnelian, chalcedony, citrine, jasper, moonstone, opal, petrified wood, quartz crystal.
Reeves	Do.
Taylor	Smoky quartz, topaz.
Terrell	Agate.
Travis	Topaz.
Trinity	Petrified wood.
Walker	Do.
Webb	Agate, jasper.
Zapata	Do.
Utah:	
Beaver	Agate, obsidian, quartz crystal.
Box Elder	Variscite.
Carbon	Agate.
Emery	Agate, chalcedony, obsidian, petrified wood.
Garfield	Agate, barite, dinosaur bone, onyx, petrified wood, jasper.
Grand	Agate, dinosaur bone, petrified wood, jasper.
Iron	Agate, geode.
Juab	Agate, geode, jasper, topaz.
Kane	Agate, petrified wood.
Millard	Fossils, jasper, obsidian.
Salt Lake	Agate, onyx.
Sevier	Agate.
Tooele	Agate, geode, obsidian.
Utah	Onyx, variscite.
Washington	Agate, alabaster, azurite, jasper.
Wayne	Agate, barite, dinosaur bone, jasper, petrified wood.

Fremont	Actinolite, agate, aventurine, garnet, jade, jasper, petrified wood, rhodonite, sapphire, serpentine.
Goshen	Jasper.
Johnson	Petrified wood.
Lincoln	Agate, petrified wood.
Natrona	Agate, amazonite, jade, petrified wood.
Platte	Agate.
Sweetwater	Agate, chalcedony, corundum, eden wood, jade, jasper, moss agate, petrified wood.
Uinta	Petrified wood.

DEFINITION OF TERMS, GRADES, AND SPECIFICATIONS

Rocks, mineral specimens, and certain organic materials, such as pearl, amber, jet, and coral, are included in gem stone statistics but are not covered in this chapter.

There is no sharp distinction between precious and semiprecious gems. In this chapter diamond, ruby, sapphire, and emerald are considered precious stones and all other gems semiprecious.

Gem stones must have qualities of splendor or beauty, durability, and rarity. Splendor in a gem depends upon transparency, brilliance, luster, and color. Luster is a function of the transparency, refractivity, and crystal structure of a mineral; durability is determined by hardness and toughness; and rarity is a major factor in determining the value of a gem.

Of the 1,500 mineral species, only about 100 have all of the attributes required in gems (*16*). Of these, the silicates furnish the greatest number, including beryl (emerald and aquamarine), tourmaline, topaz, and quartz (agate, chalcedony, and opal). Oxides, such as corundum (ruby and sapphire), comprise the second largest group. Sulfides, carbonates, phosphates, and sulfates are of little importance. The most important commercial gem stone, diamond, is an element (carbon). Other elements used as gem materials include native gold, copper, and silver.

Gem materials are classified into group, species, and variety (*4*). Group refers to two or more gem minerals that are similar in crystal structure and physical properties but have different chemical properties. The individual members of the group are the species. Varieties of a species have similar crystal structure and chemical characteristics but differ in color.

TECHNOLOGY

Geology

The large number of gem minerals implies a variety of occurrences and origins (*24, 30*).

Gem minerals are formed principally by precipitation from aqueous solutions, crystallization from magmas, and metamorphic processes.

Many gem stones, including beryl, tourmaline, topaz, spodumene, and quartz, are formed in igneous rocks, principally pegmatites. Kimberlite pipes and dikes are the major sources of diamond. Emerald and garnet occur in metamorphic rocks.

Most gems are dense, resistant to abrasion, and chemically inert. Ruby, sapphire, tourmaline, agate, jade, zircon, diamond, garnet, and quartz are obtained commercially from alluvial deposits.

Mining

Gem stone mining in the United States consists essentially of the activities of thousands of amateur "rockhounds." Most gems are mined with hand picks and shovels and are hand sorted.

Some owners of gem stone claims use power-operated dirt-moving equipment to uncover the gem material and open their land to collectors for fees. In some localities the uncovered material is screened and washed by panning; in other areas the gem-bearing material is sorted directly by hand.

Gem stone placer-mining methods are similar to those used in gold placer mining. In the better equipped mines the topsoil is stripped with bulldozers and wheel scrapers, and the gem-bearing gravel is treated in washing plants. The final separation is made with grease tables, electrostatic separators, and hand picking (*21*, *29*).

Underground mining methods are used in the diamond "pipe" mines of South Africa. The ore is crushed and concentrated by heavy-medium separation, concentrating pans, and jigs. The final separation is done on grease tables (*15*).

Diamond-bearing gravel deposits in shallow coastal waters off the South-West African coast are mined by suction dredge and the gravel pumped to a shipboard plant where it is beneficiated and the diamond recovered (*6*, *17*).

Cutting and Polishing

Usually amorphous and cryptocrystalline gem materials are cut or carved and polished as shown in figure 1.

Cutting of cabochons comprises four main operations, sawing, grinding, sanding, and polishing (*1*). Sawing is done when cutting large, rough masses or preliminary to polishing large, flat surfaces. Two general methods are "mud" sawing with a creamy mixture of silicon carbide powder, water, and glycerin and "diamond charged" sawing with a mixture of diamond dust and oil. Grinding is accomplished by using different grades of grinding wheels, depending upon the hardness of the gem material. Sanding removes the large scratches made in grinding. Disk, belt, or drum sanders, made of felt cloth or canvas coated with an abrasive grit such as silicon carbide and aluminum oxide, are used. Polishing is usually done on a revolving hard-felt lap or muslin or leather buff, in either horizontal or vertical position. Polishing agents include tin oxide, tripoli, cerium oxide, alumina, and rouge.

Tumbling, an inexpensive method of polishing gems of irregular shape, is done in lined and unlined containers, using a polishing medium with or without water (*30*). The irregular shapes produced are called baroque gems.

Some precious gems are beautiful in their natural form, but usually their appearance is improved by cutting and polishing in one or more of the cuts shown in figure 2.

Facet cutting is confined mainly to transparent gems having a hardness of 7 or more. The "brilliant" cut, most commonly used in faceting, has 58 facets, 33 above the circle "girdle" and 25 below it, arranged in eightfold symmetry. (See fig. 1.)

Manufacture of Synthetic Gems

The flame-fusion process, developed by Verneuil in 1902, made possible the synthesis of ruby and later of sapphire, spinel, rutile, and beryl. This process consists of growing a single crystal in a simple, inverted, oxyhydrogen blowpipe. In manufacturing synthetic gems, pure oxides of aluminum and titanium and, sometimes, coloring oxides are charged at the top of a small furnace and melted as they pass through an oxygen-hydrogen flame. The molten alumina is solidified on a fire-clay peg as a carrot-shaped crystal known as a boule, usually ½ to 1 inch in diameter, 2 to 4 inches long, and weighing 75 to 250 carats. The boule is then heat-treated or split to relieve the inherent strain, cut, and polished into gems.

Other processes used to synthesize gem materials include—

1. Crystal growth from solution (quartz, beryl, sapphire, garnet).
2. Solid-state reaction and phase transformation (lapis lazuli).
3. Vapor-phase reaction (greenockite, marcasite).
4. High temperature and pressure (ruby, sapphire, diamond).

A guide to the various stones used in jewelry is given in table 2.

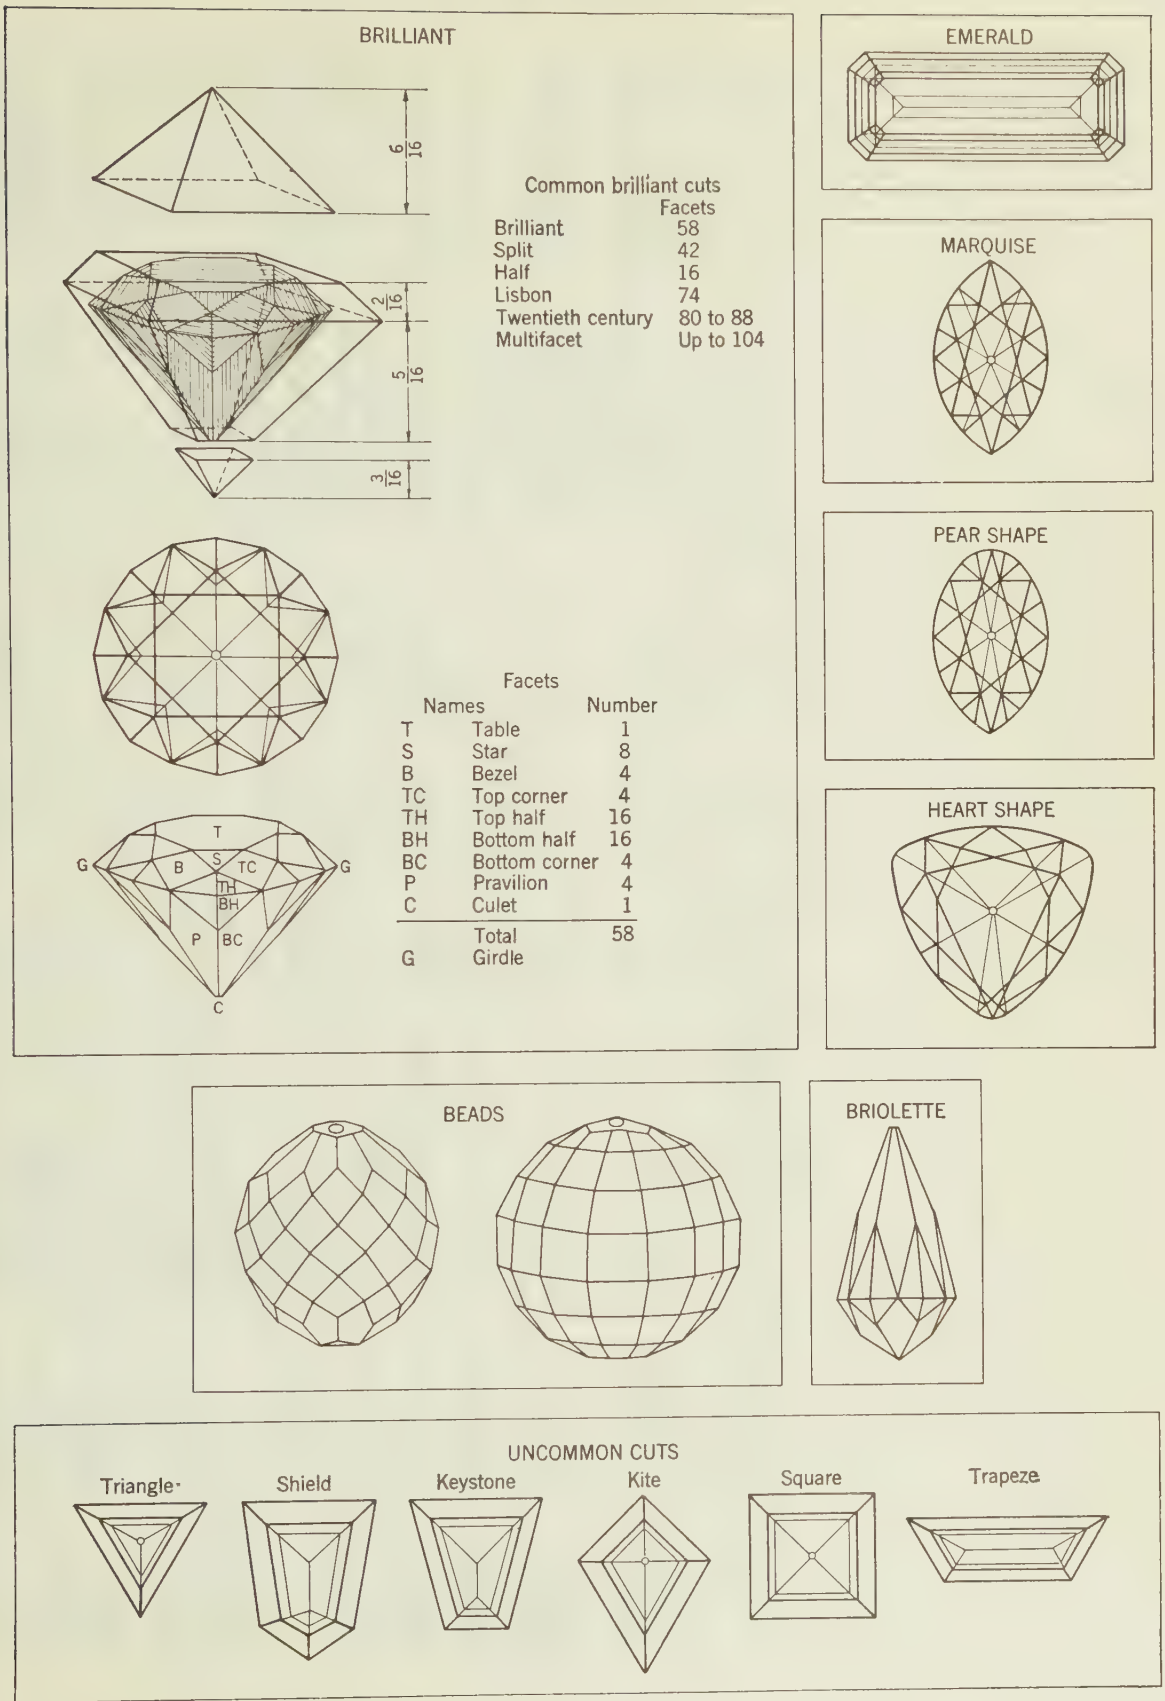

FIGURE 1.—Principal Forms of Crystalline Gem-Stone Cuts.

TABLE 2.—*Reference guide to the various stones used in jewelry*

Name	Composition	Color	Resistance to wear	Practical size [1]	Cost [2]	Refraction	Refractive index	May be confused with—	Recognition characters
Beryl:									
Aquamarine	Beryllium aluminum silicate.	Blue-green to light blue.	Good	Any	Medium	Double	1.58	Synthetic spinel, blue topaz.	Double refraction, refractive index.
Emerald	do	Green	Poor	Medium	Very high	do	1.58	Soldered emerald, glass, tourmaline, peridot, green garnet.	Emerald filter dichroism, refractive index.
Emerald (synthetic).	do	do	do	Very small	High	do	1.58	Genuine emerald	Flaws, brilliant fluorescence in ultraviolet light.
Golden	do	Yellow to golden	Good	Any	Medium	do	1.58	Quartz topaz, precious topaz, glass, doublets.	Refractive index, double refraction.
Morganite	do	Pink to rose	do	do	Low to medium.	do	1.58	Kunzite, tourmaline, pink sapphire.	Refractive index.
Chrysoberyl:									
Alexandrite	Beryllium silicate	Green by day, red by artificial light.	do	Russian (small); Ceylon (medium).	High	do	1.75	Synthetic	Dichroism, inclusions in synthetic sapphire.
Catseye	do	Greenish to brownish	Excellent	Small to large	do	do	1.75	Quartz	Gravity and translucence.
Chrysolite	do	Yellow, green, brown.	Good	Medium	Medium	do	1.75	Tourmaline, peridot	Refractive index, silky.
Corundum:									
Ruby	Aluminum oxide	Rose to deep purplish red.	do	Small	Very high	do	1.78	Synthetic	Inclusions and shape of flaws.
Sapphire	do	Blue	do	Medium	High	do	1.78	Synthetics including spinel.	Inclusions, double refraction, dichroism.
Sapphire (fancy)	do	Yellow, pink, white, orange, green, violet.	do	Medium to large.	Medium	do	1.78	Synthetics, glass and doublets.	Inclusions, double refraction, refractive index.
Sapphire and ruby stars.	do	Red, pink, violet, blue, gray.	do	do	High to low	do		Star quartz, synthetic stars.	Shows asterism, color on side view.
Sapphire or ruby (synthetic).	do	Yellow, pink, blue, red, white, green, violet.	do	Up to 20 carats	Low	do	1.78	Synthetic spinel, glass	Double refraction, refractive index.
Diamond	Carbon	White, blue-white, yellow, brown, green, red, blue, pale.	Excellent	Any	High	Single	2.42	Zircon, titania	High index, dispersion, single refraction, hardness, cut, luster.
Feldspar:									
Amazonstone	Alkali aluminum silicate.	Green	Fair	Large	Very low			Jade	Cleavage sheen, vitreous to pearly, opaque.
Labradorite	do	Gray with blue sheen	do	do	do			Brazilian butterfly	Do.
Moonstone	do	White	do	do	do		1.52	Glass or white onyx	Blue sheen, opalescent.
Garnet	Variable silicate	Brown, black, yellow, green, ruby red.	Good to fair	Small to medium.	Low to medium.	Double (strong).	1.79–1.98	Synthetics, spinel, glass.	Double refraction, wear on facet edges, light-colored varieties are transparent.
Jade	Complex silicate	Green, red, black, white, mauve.	Good	Large	Low to very high.		1.65–1.68	Onyx or glass	Luster of polished surface, translucent to opaque.

Olivine: Peridot	Iron magnesium silicate.	Yellow, green	Fair	Any	Medium	Double (strong).	1.68	Tourmaline, chrysoberyl.	Strong double refraction, low dichroism.
Opal	Hydrous silica	Colors flash in white, gray, black, red, yellow.	Poor	Large	Low to high	Single	1.45	Glass	Color changes.
Quartz:									
Agate	Silica	Any colors	Good	do	Low			do	Crystalline, irregularly banded.
Amethyst	do	Purple	do	do	Medium	Double	1.55	do	Refractive index and double refraction, transparent.
Cairngorm	do	Smoky	do	do	Low	do	1.55	do	Do.
Citrine	do	Yellow	do	do	do	do		do	Do.
Crystal (rock)	do	Colorless	do	do	do	do	1.55	do	Do.
Jasper	do	Uniform or spotted, red, yellow, brown, green, blue.	do	do	do			do	Opaque, vitreous.
Onyx	do	Many colors	do	do	do			do	Uniformly banded.
Rose	do	Pink, rose red	do	do	do	do	1.55	do	Refractive index and double refraction, transparent.
Spinel	Magnesium aluminum oxide.	Red, blue, lilac, orange, yellow, purple, green.	Medium	Medium	Low to medium.	Single	1.72	Synthetic sapphire, garnet.	Refractive index, single refraction, inclusions.
Spinel (synthetic)	do	Blue, white, light blue, yellow, gray, green, alexandrite colors.	Good	Up to 40 carats	Low	Double	1.73	Spinel, sapphire, aquamarine, topaz, alexandrite.	Weak double refraction, lack of dichroism, refractive index.
Spodumene:									
Kunzite	Lithium aluminum silicate.	Pink to lilac	Poor	Any	Medium	Double	1.66	Pale amethyst, morganite.	Refractive index, transparent.
Hiddenite	do	Yellow to green	do	do	do	do	1.66	Synthetic spinel	Do.
Topaz (precious)	Complex silicate	White, blue, yellow, pink, red, green.	Fair	White and blue any size. Yellow and pink to medium.	Low to medium.	do	1.62	Beryl, aquamarine, quartz, topaz.	Refractive index.
Tourmaline	do	Red, pink, green, blue, wine, brown, yellow.	do	Green and red to 50 carats. Others medium.	do	do	1.63	Peridot, beryl, corundum, glass.	Double refraction, refractive index.
Turquoise	Copper aluminum phosphate.	Blue to green	do	Large	Low	do	1.63	Glass or composition	Difficult if matrix not present, matrix usually limonitic.
Zircon	Zirconium silicate	White, blue, brown, yellow, green.	Poor	Small to medium.	Low to medium.	Double (strong).	1.79–1.98	Diamond, synthetics	Double refraction, wear on facet edges.

[1] Small—up to 5 carats; medium—up to 50 carats; large—over 50 carats.
[2] Low—up to $5 per carat; medium—up to $100 per carat; high—over $100 per carat.

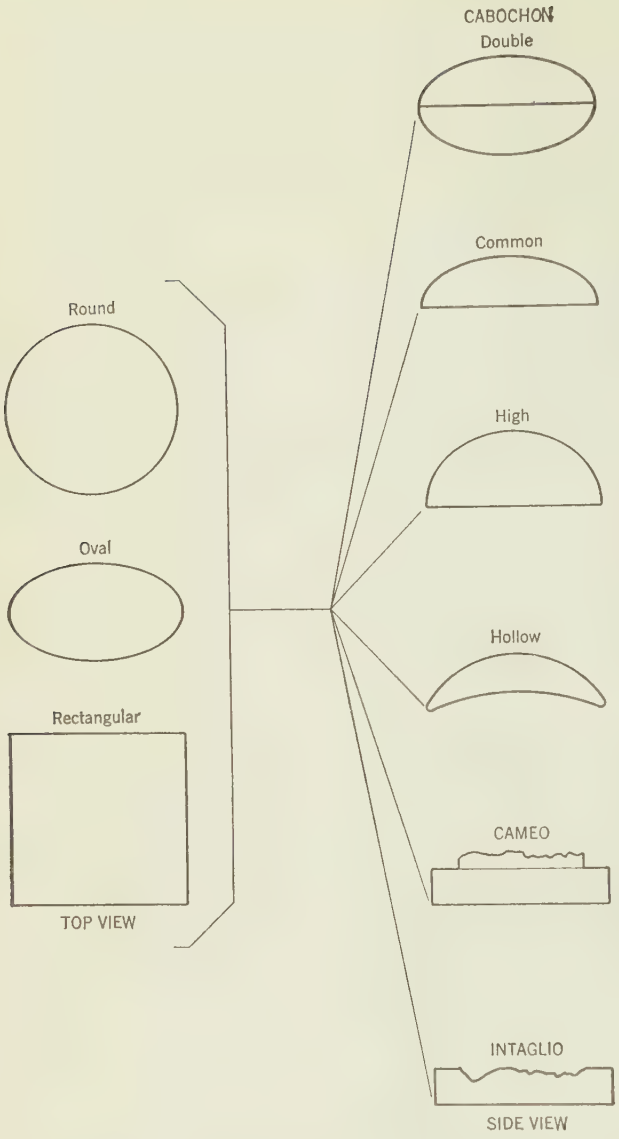

FIGURE 2.—Cryptocrystalline Gem-Stone Cuts.

The color of many natural stones may be changed by heating, dyeing, or exposure to X-rays, cyclotron bombardment, deuteron bombardment in nuclear reactors, or cathode rays (*7*, *25*).

USES

Virtually all gem stones are used for decorative purposes in jewelry, for statuettes, vases, and other art objects, and for exhibit in collections.

Some low-quality gem diamond is used as industrial diamond when the value is about the same. Tourmaline is used as a simple laboratory polariscope, as a piezoelectric material, and in gages for measuring extremely high pressures. Agate is made into mortar and pestle sets, knife edges for balances, textile rollers, and spatulas. Originally, ultramarine blue pigment was made from lapis lazuli. Other gem materials are or have been used by industry for minor applications.

Many people purchase precious stones because they represent concentrated wealth that can easily be transported, hidden, and sold or traded.

BYPRODUCTS AND COPRODUCT RELATIONSHIPS

Beryl, tourmaline, spodumene, and gem quartz occasionally are coproducts of mica, feldspar, quartz, and other pegmatite minerals. Gem-quality diamond is a coproduct of industrial diamond at most mines. Frequently, gem stones are byproducts of other commodities. For example, diamond has been recovered from gold dredges, turquoise from copper mines, agate and petrified wood from gravel pits, and gem garnet from abrasive garnet operations.

ALTERNATE MATERIALS

Plastics, glass, metals, wood, paper, and other materials are substituted for gem stones in costume jewelry. Natural gems having little color are made to appear darker by cementing colored glass on a natural stone.

Many synthetic gem stones compete with natural gems. They include ruby, sapphire, spinel, rutile, and emerald. Industrial diamond also is manufactured, but crystals large enough for gems have yet to be produced.

SECONDARY SOURCES AND RECOVERY

Gem stones recovered from jewelry are recut and set in jewelry of modern design. Pieces resulting from cutting fine gem stones are processed into gems of lower quality or are used for tumbled baroque gems.

RESERVES

The United States has no known large resources of precious gem stones. Occasional finds of diamond have been made but no great diamond pipes or alluvial deposits similar to those of Africa have been discovered.

Numerous domestic deposits of semiprecious gem stones are known and have been mined during the past decades. However, no systematic evaluations of the magnitude of these deposits has been done, and no positive statement can be made about them.

The world gem diamond reserve is estimated to be 100 million carats. Nearly all of this quantity is in Africa. Possible offshore underwater deposits have not been considered in making the estimate. Underwater deposits off the coast of southwest Africa being prospected will probably add to the world reserve estimate. Some production of gem diamond is reported in the U.S.S.R., but no information on reserves is available. World reserve data on other precious and semiprecious stones are lacking.

SOURCES OF STATISTICAL INFORMATION

The Bureau of Mines obtains domestic gem stone production and supplemental data from an annual canvass of all known major producers. The Bureau of the Census, U.S. Department of Commerce, collects data on imports, exports, and reexports of gem stones on a monthly basis.

PRODUCTION AND TRADE

In 1963, production came primarily from Oregon, California, Texas, Arizona, Wyoming, Nevada, Utah, and Washington. The estimated value of U.S. production was more than $1.4 million, compared with less than $250,000 in 1900. Table 3 gives the estimated value of gem stone output in the United States; table 4 shows world production of gem diamond by countries; and table 5 shows precious and semiprecious stones imported for consumption in the United States.

Imports of natural, uncut precious and semiprecious gem stone are duty free. Duty rates for cut but unset precious gem materials follow: Diamond under 0.5 carat, ruby, sapphire, and synthetic gem stone quality material, 8 percent ad valorem; diamond over 0.5 carat, and marcasites, 10 percent ad valorem; emeralds, 3 percent ad valorem; other precious stones, 5 percent ad valorem; and precious stone not otherwise provided for in any other import category, 15 percent ad valorem. Rock crystal (clear quartz crystal) is dutiable at 21 percent ad valorem.

TABLE 3.—*Estimated value of U.S. production of gem stones*

Year	Value (thousands)	Year	Value (thousands)
1954–58 (average)	$849	1961	$1,309
1959	1,184	1962	1,296

PRICES

The price of a finished gem stone usually is determined by demand and by its beauty, durability, rarity, freedom from defects, and perfection of cutting. An additional factor in establishing the price of gem diamond is the control over output and prices exercised by the Diamond Corp., Ltd.

In 1963, the range of retail prices for gem diamond was 0.25 carat, $72 to $340; 0.5 carat, $220 to $600; 1 carat, $575 to $1,650; 2 carats, $1,380 to $5,000; 3 carats, $2,880 to $9,900. Table 6 gives average prices paid for gem diamond and emerald per carat by importers.

TABLE 6.—*Average prices per carat of gem diamond and emerald imported for consumption in the United States.*

	1954–58 (average)	1959	1960	1961	1962	1963
Diamond:						
Rough or uncut	$70.65	$59.74	$64.09	$50.42	$72.15	$74.23
Cut but unset	104.52	94.20	97.30	93.67	90.79	92.35
Emerald: Cut but unset	30.92	27.56	18.01	9.19	14.22	10.90

Various transparent minerals, such as andalusite, diopside, epidote, kyanite, and sphene, when cut command a retail value of $2 to $50 per carat. The actual value depends on the size and quality of the stone. Prices of opaque minerals range from $5 to $30 per stone in the 10- to 15-carat size range. Cut synthetic emerald, depending on quality, ranges from $20 to $100 for a 1-carat stone and from $25 to $150 for a 2-carat stone. Cut synthetic spinel runs from $8 to $20 per carat in the size range from 1 to 10 carats. Boules of synthetic sapphire, spinel, and ruby sell for under 10 cents per carat.

TAXES

A depletion allowance of 15 percent is granted on domestic and foreign gem stone production.

An excise tax of 10 percent is imposed by the Government on the retail sales value of set or unset gems. Many States have a general sales tax ranging from 1 to 3 percent in addition to the Federal tax. Some States assess personal property taxes each year on privately owned jewelry and gem stones.

RESEARCH

Research on the production of synthetic gem stones is done by Linde Air Products Co., a division of Union Carbide Corp.; Stuart Laboratories, Inc.; National Lead Co.; Chatham Research Laboratories; Bell Telephone Laboratories; and General Electric Co. One result of this research is the development of synthetic gems with colors not found in nature. The Diamond Research Laboratory at Johannesburg, Republic of South Africa, conducts basic and applied research on gem diamonds.

Research also is being conducted on determining the conditions necessary to synthesize pure silicates, on developing hydrothermal techniques for growing sapphire crystals, on the use of ultrasonic vibrations for drilling and cleaning precious stones, and on developing automatic polishing machines (*22*).

OUTLOOK

The demand for gem diamond, especially in the larger carat weights, can be expected to rise because of increasing personal income of the population of the United States and other industrialized countries. Because of the increasing demand for precious stones for both adornment and investment, prices will continue to increase. The development of new diamond resource areas and the reactivation of older mine properties will assist the industry in meeting current and future demands.

The semiprecious gem requirements of the United States will continue to be met by the efforts of individual domestic gem stone collectors and mineral clubs along with imports of these materials from other nations The devel opment of commercial domestic semiprecious gem stone lapidaries and cutters will remain minimal owing to the high labor costs and relatively low value of the finished materials. However, gem and mineral collecting, cutting, and polishing will continue as a very popular hobby with a large segment of the population.

The demand for synthetic gem materials will continue to increase. Synthetic gem stone will find increasing use for mounted jewelry, and industrial demands will create new uses for these synthetics. Synthetic materials such as quartz crystal, ruby, and sapphire have been successfully used in industrial applications.

PROBLEMS

The lack of known domestic gem stone deposits and reserves that can be economically exploited remains the primary problem associated with this commodity.

Basic gem stone production statistics are difficult to obtain owing to the large number of unknown individual collectors. Because of this situation, no reliable estimate of gem stone production is available.

The development of a larger cutting and polishing industry is hampered by deficiency of well-developed gem deposits.

GERMANIUM

By Donald E. Moulds [1]

GERMANIUM is produced commercially as a byproduct in mining and refining ores of other metals. The major domestic source of germanium has been the Tri-State zinc district of Missouri-Kansas-Oklahoma and the Illinois-Kentucky fluorspar district. The Tsumeb mine in South-West Africa and the Prince Leopold mine in the Congo (Léopoldville) are the major sources of free world supply. Fume and residues from base metal refining and coal ash from coal-burning operations contribute small amounts.

Industrial organizations engaged in producing and refining germanium are also few, but the capacity of the industry is ample to assure a continuing supply well able to meet foreseeable demand. Companies engaged in manufacturing semiconductor components are relatively numerous and widely scattered in the United States and foreign industrial areas.

The only significant industrial use for germanium is as a semiconductor component for electronic and electrical devices. The rapidly expanding use of these devices in the field of communications, power transmission, data processing, missile guidance, and astronautics has been accompanied by major advances in component manufacturing techniques and utilization; these advances have significantly slowed the rate of consumption of germanium per component.

The vulnerability of germanium to substitution by other semiconductors with comparable performance characteristics in the highly competitive electronics industry necessitates a continuing emphasis on germanium research both in the semiconductor field and in other potential applications. In addition an ample supply must be maintained at a competitive price.

BACKGROUND

In 1871 Mendeleef, a Russian scientist, predicted the existence of an element, eka-silicon, occupying number 32 in the periodic table. Fifteen years later, Clemens Winkler, a German scientist, isolated the element from the mineral argyrodite and named it germanium in honor of his native country. Investigation of the properties of germanium confirmed the predictions of Mendeleef (*6*).[2]

Germanium remained little more than a scientific curiosity until the early 1920's when extensive studies were conducted on possible applications of the substance. In 1922 the therapeutic value of germanium oxide in treating anemia was reported. The first commercial producer of germanium dioxide was the Otavi Company in Frankfurt, Germany, in 1930. The source of the material was germanite ore obtained from the Tsumeb mine in the then-German colony of South-West Africa.

The zinc ores of the Kansas-Missouri-Oklahoma area contain a small amount of germanium which constitutes an impurity in refined zinc and had to be removed by a difficult and costly process. The Eagle-Picher Co. initiated a research program to determine what, if any, commercial application could be developed for this byproduct. Fundamental research programs at Bell Telephone Laboratories and Purdue University developed the semiconductor application for germanium and by 1941 a germanium-recovery facility was in operation in connection with the Henryetta, Okla., zinc smelter of The Eagle-Picher Co.

The semiconductor properties of germanium were first utilized extensively for crystal diode rectifiers during World War II. In 1948 the germanium transistor was developed, and expanded research and availability of high-purity germanium has revolutionized the communications industry. The semiconductor devices currently utilized—diodes, transistors, and rectifiers—have permitted miniaturization of radios,

780-887 O—65——25

television, hearing aids, and telephone dialing equipment and have allowed major advances in astronautics, missile guidance, and worldwide communications.

SIZE, ORGANIZATION, AND GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

Shipments of germanium semiconductor devices in the United States in 1963 approached 550 million units valued at $209 million. Some 130 plants are engaged in manufacturing the specialized germanium diodes, rectifiers, and transistors required in a wide scope of electrical equipment.

The U.S. producers of germanium from domestic and foreign source material are American Metal Climax, Inc., Carteret, N.J.; American Zinc Company of Illinois, Fairmont, Ill.; The Eagle-Picher Co., Henryetta, Okla.; and Sylvania Electric Products, Inc., Towanda, Pa. In addition, United Minerals and Chemical Corp., New Brunswick, N.J., and Penn Rare Metals, Revere, Pa., a division of Kawecki Chemical Co., produce germanium from scrap processing. The three major representatives of foreign germanium producers marketing imported metal and dioxide in the United States are The African Metals Corp., American Metal Climax, Inc., and Harmon Lichtenstein and Co., all with offices in New York City.

The Tri-State zinc-lead mining district of Kansas, Missouri, and Oklahoma has been the major source of the domestic production of germanium since The Eagle-Picher Co. started commercial production in 1941. Zinc concentrate from the Illinois-Kentucky fluorspar district is treated at Fairmont, Ill., for recovery of germanium.

The Tsumeb Corp., Ltd. produces germanium from the copper-lead-zinc ores of the Tsumeb mine in South-West Africa by selective flotation and refining to germanium dioxide. The dioxide is further processed to metal at the Carteret, N.J. plant of American Metal Climax, Inc.

Union Minière du Haut-Katanga produces germanium from the copper-zinc ores of the Katanga area of the Congo (Léopoldville). The germanium is contained in concentrates collected from the fume and dusts resulting from copper smelting and shipped to Belgium for refining. Union Minière operates the largest germanium refinery in the world at Olen, near Antwerp, Belgium, through its affiliate the Société Générale Metallurgique de Hoboken. The capacity of the plant is 135,000 pounds of electronic-grade germanium dioxide per year (65 percent germanium).

The Société de la Vieille Montagne has produced germanium at Balen, Belgium, since 1952 as a byproduct of its zinc-refining operations. In the United Kingdom, Johnson, Matthey and Co. began producing germanium in 1950 from coal flue dust obtained at its producer-gas plant. The zinc plant of Montevecchio near Venice, Italy, produces a small quantity of germanium from zinc-refining operations. West Germany and Japan also are producers of germanium from zinc concentrates, coal dusts, refinery residues and other source materials. Little is known of the germanium industry of the U.S.S.R., but the wide use of semiconductors and extensive published research data indicate a major output from the complex ores of the Kazakhstan area.

DEFINITIONS OF TERMS, GRADES, AND SPECIFICATIONS

Germanium is metallic-looking but displays the physical and chemical properties of a metal only under special conditions. It is a semiconductor with properties ranging between those of a metal and of an insulator. Structurally, germanium has the cubic symmetry of the diamond crystal lattice and four valence electrons. Some of the more distinctive properties of germanium follow (*5*):

Atomic weight	72.60
Density at 25° C, g/cm³	5.32
Melting point, °C	940
Boiling point, °C	2,700
Band gap at 0° K, electron-volts	0.75
Intrinsic resistivity at 27° C, ohm-cm³	47
Electron mobility, drift, cm²/volt/sec	3,800
Hole mobility, drift, cm²/volt/sec	1,800
Debye temperature, °K	362
Thermal conductivity, cal/sec/cm²/°C	0.15
Dielectric constant	15.7
Specific heat at 25° C, val/g/°C	0.074
Bulk rigidity modulus, dyne/cm²	1.3×10^{12}
Thermal expansion coefficient (linear) at 25 °C per °C	6.1×10^{-6}
Latent heat of fusion, cal/mol	8,300

Germanium is available in three forms: as reduced ingots, purified ingots, and single crystals. Standard ingots are 15 to 17 inches long and weigh approximately 1,750 grams. Mono, or single, crystals grown are supplied in sizes up to 3 inches in diameter and weights up to 2,000 grams. These crystals are normally grown in the 1:1:1 orientation.

The standard measurement of purity of electronic-grade germanium is resistivity. These measurements are made using a four-point probe on an abraded surface at 25° C. In the polycrystalline form, measurements are made along the bottom of the ingot.

Specifications for marketable electronic-grade germanium have changed as the requirements of the electronic industry became more rigid. It

is typical for germanium to be offered to consumers under the following minimum resistivity specifications:

As-reduced	5 ohm cm minimum.
Purified	40 ohm cm minimum.
Monocrystalline	40 ohm cm minimum.

Germanium is also offered commercially in the form of monoxide, as dioxide, and compounded with other metallic and nonmetallic substances.

Test procedures for determination of volatile content and bulk density of germanium dioxide have been accepted by the American Society for Testing and Materials (*2*).

TECHNOLOGY

Germanium is obtained commercially as a byproduct of zinc production and from germanium-bearing minerals as a coproduct of base-metal refining (*3*).

Geology

There are no native occurrences of germanium, and its abundance in the earth's crust is 1 part in 150,000 or 6.7 parts per million. The more important germanium minerals follow. Germanite, $7CuS \cdot FeS \cdot GeS_2$, is a complex mineral found mainly at Tsumeb, South-West Africa, in isolated pockets in the main copper-lead-zinc ore body. Its average germanium content is 5 percent. Argyrodite, $4\ Ag_2S \cdot GeS_2$, from which Winkler first isolated germanium, occurs at the Himmelfurst and other mines at Freiberg, Saxony, and at Aullagus, Bolivia. Its germanium content is between 5 and 7 percent. Canfieldite and ultrabasite are also found at these localities. The former contains 1.8 to 6.5 percent germanium and the latter contains 2.2 percent. Renierite, $(Cu,Fe)_3(Fe,Ge,Zn,Sn)S,As)_4$, is found mainly at the Prince Leopold mine at Kipushi, the Congo (Léopoldville), and at the Tsumeb mine in South-West Africa. The germanium content ranges from 6.37 to 7.80 percent.

The most common occurrence of germanium is in minute quantities within the molecular structure of other minerals. It occurs most abundantly in sphalerite (ZnS) in quantities ranging from traces to tenths of 1 percent. Cinnabar sometimes contains germanium in tenths of 1 percent and enargite up to 0.1 percent. Pyrargyrite from the silver mines of Bolivia contains up to 0.1 percent, and some tin-bearing sulfides contain 0.5 percent. Germanium has also been said to occur in calamine, pyrites, euxenite, cassiterite, and tantalum and columbium ores. However, the amounts recorded are small, usually about 0.001 percent or less.

From the extensive studies made on the germanium content of coal it is possible to set down some broad generalizations on the subject:

1. Coals with a high vitrain (woody coal) content are much richer in germanium than coal with a low vitrain content.
2. Low-ash coals are richer in germanium than coals with a high ash content.
3. Geologically older coals usually have a lower germanium content than more recent coals.
4. Germanium is believed to be associated with the organic matter and not the mineral matter in coal.
5. The germanium is usually concentrated in the top or bottom few inches of coal beds.

Techniques used for the analysis and detection of germanium are discussed in detail in germanium literature concerning its occurrence in coals (*1, 4, 9*). The semiquantitative spectrographic method provides the most rapid means of obtaining information on the magnitude of germanium concentration. For more precise estimates of germanium concentration the quantitative spectrographic method provides a sensitive, rapid, and reliable technique. Analytical chemistry of germanium by wet methods is based on the separation of germanium from most interfering elements by distillation as volatile germanium chloride. Then the germanium is determined in the distillate by analytical methods that include gravimetric, volumetric, or colorimetric procedures. The spectrophotometric method of Cluley (*1*), which utilizes phenylfluorenone, is widely used. The spectrophotometric procedure is more sensitive than the quantitative spectrographic method, but it requires more involved and time-consuming sample preparation.

In the metallugical recovery of germanium from the source materials, various processes are used to obtain a product suitable for recovery of the germanium as a crude tetrachloride. The subsequent process of refining is quite similar for all production plants.

Metallurgy

In the metallurgical recovery of germanium from Tri-State zinc sulfide concentrate, the sulfur is first removed by roasting, and the zinc germanium, and cadmium are converted to oxides. The oxides are given a chloridizing roast to convert cadmium and germanium to chlorides which are volatilized. These are condensed and collected electrostatically to yield a

product from which germanium can be distilled as the tetrachloride.

Zinc ores from the Illinois-Kentucky district are concentrated and sintered in the same manner as the Tri-State ores. The germanium reports in the byproduct fume which is leached with sulfuric acid to dissolve zinc and cadmium and leave a sludge containing germanium. Germanium is then dissolved by hot, strong sulfuric acid and precipitated with hydrogen sulfide. The sulfide precipitate is roasted and the germanium oxide is reacted with strong hydrochloric acid to form germanium tetrachloride.

The copper-zinc ores of Katanga contain germanium as the mineral renierite. In selective flotation of the ores, the renierite reports with the copper concentrate. Part of the renierite is then recovered by magnetic separation. This product is treated in an electric furnace to obtain a fume containing germanium dioxide. Germanium-bearing fume and dust are also recovered from the copper smelting. They are then baked with sulfuric acid and leached to obtain a germanium-bearing solution from which, after oxidation, the germanium is precipitated with magnesia and copper hydrate to form a concentrate which is then shipped to Belgium for further refining.

Flue dusts are smelted with soda ash, lime, copper oxide, and coal dust to form a regulus and slag. The regulus, containing germanium, is reacted with chloride under a dilute solution of ferric chloride, and the crude germanium tetrachloride is distilled. Arsenic chloride accompanying the germanium is eliminated by refluxing with copper turnings.

Controlled purity is essential in germanium for electronic uses. Less than 1 part per 100 billion of some impurities has an observable effect. Germanium tetrachloride is purified by distilling it from strong hydrochloric acid solution. After distillation it is hydrolyzed in ice water to obtain pure germanium dioxide, which is washed completely free of chloride and is then ready for reduction to the metal.

Germanium dioxide is reduced by heating in hydrogen. The dioxide is packed in graphite boats and heated to 650° C in an electric furnace in a current of hydrogen until no more water is evolved. The hydrogen is then replaced by helium or nitrogen, and the temperature is raised to 1,000° C to melt the resulting powder.

When germanium is used as a semiconductor, it is necessary to have an ultra-high purity which is measurable in parts per billion and which is achieved by zone refining. A germanium ingot 12 to 20 inches in length and 1 to 1½ inches in diameter is passed through a series of induction-coil heaters, each of which produces a molten zone. Relatively pure germanium crystallizes at the trailing edge of each molten zone, and impurities remain in the molton zone and are gradually isolated toward one end as the bar moves through the heaters. After the desirable number of passes are made through the induction stages, the end of the ingot containing the impurities is cut off.

The ultrapure germanium ingot thus produced is polycrystalline, and for semiconductor use it must be in the form of a single crystal. Two methods of single-crystal growth were developed for growing germanium crystals. The first, originated by Czochralski, is called the vertical pulling method. A crystallographically oriented seed-crystal is dipped into molten germanium in a graphite crucible and slowly withdrawn. Then, by adjusting the heat input and heat losses, and under proper conditions and synchronization, the germanium will grow on the seed and extend its crystal lattice until the charge has been converted to one crystal.

The second method, called the horizontal or zone-leveling technique, is a modification of zone melting. The crystal seed is placed at one end of a horizontal, carbon-coated silica crucible filled with ultrapure polycrystalline germanium. The whole may be converted into a single crystal with the controlled addition of a desired impurity by carefully moving a molten zone toward the seed, melting into it, and then slowly withdrawing the molten zone.

USES

The major use of germanium is in manufacture of semiconductor devices. The advantages of these devices—extremely small size and weight, small current consumption and immediate availability of operation, and long operating life, ruggedness, and mechanical stability—have resulted in a wide range of application in the field of communications, power rectification, data processing, astronautics, and missile guidance.

Germanium has a potential use in the production of glass with special properties. Glass in which all or part of the silicon dioxide has been replaced by germanium dioxide displays an unusually high index of refraction and is useful for wide-angle camera lenses and microscope objectives. Glass containing magnesium germanate can transmit infrared radiation over broad regions of the spectrum and is used in infrared spectroscopes and other infrared optical instruments. Germanium-magnesium phosphors have been used in fluorescent lights.

Germanium gives increased hardless and strength to copper, aluminum, and magnesium and improves their rolling properties. Ger-

manium-gold alloys have been experimented with as dental alloys. The alloys of the germanium-gold series can be used as precision castings since they expand on cooling. The addition of small percentages of germanium to gold sharply reduces the melting point, and the 12-percent germanium eutectic has a melting point of 356° C. This may be used to advantage as a gold solder and in jewelry manufacture, because the gold color remains.

Germanium is beneficial as a storage battery solution additive in producing more usuable ampere-hours, especially in intermittent-use lead-acid batteries. Transistorized automobile ignition systems are currently in the demonstration stage (*5*).

BYPRODUCTS AND ALTERNATE MATERIALS

Germanium is a byproduct closely associated with base metals and dependent upon these metals to bear the major share of the cost of extraction and processing. The predominate use of germanium as a semiconductor incorporates a vulnerability to direct substitution by other semiconductors with comparable performance characteristics such as high-purity silicon and certain tellurium, selenium, indium, and gallium bimetallics.

Germanium diodes, transistors, and rectifiers have replaced the vacuum tube or electron tube in many applications where cost-performance ratios have been competitive.

SECONDARY SOURCES

The germanium secondary metal market is currently negligible; there is some small-scale salvage and marketing of obsolete devices. New scrap generated in manufacture of semiconductor devices such as cuttings, grindings, and rejections is usually returned to the germanium producers for reprocessing on a toll basis. Currently reprocessed scrap represents up to 60 percent of that shipped to manufacturers.

RESERVES

The known occurrences of mineral deposits valued chiefly for germanium are of small significance and none are presently utilized for recovery of germanium. The small percentage of germanium (0.01 to 0.1 percent) associated with ores of zinc and other base metals is economically recoverable only because in the process of refining the host metals the germanium is concentrated in byproducts to a degree susceptible to recovery and refining at an acceptable cost.

Variation in content of ores and recovery of germanium is not presently known to the degree necessary for compilation of world resources. The byproduct relationship of germanium to base-metal ores in the Congo (Léopoldville), South-West Africa, and the United States indicates, however, that the potential is adequate to meet any foreseen demand.

A relatively large potential source of germanium is the germanium compounds found in amounts ranging from 1 to 4 percent in certain coal ashes and flue dusts. It has been estimated that in the United Kingdom alone 2,000 tons of germanium yearly may be present in stack gases, flue dusts, and ashes at plants burning germaniumiferous coal.

Coal deposits in the United States have been extensively studied (*9*). Data on germanium content of coals in West Virginia, Illinois, and Kansas has been reported (*1*) and a large potential supply exists in certain coals containing 0.05 to 0.1 percent germanium in the ash. Research on extraction is well advanced toward an economic method of commercial production in event of a substantial increase in demand.

SOURCES OF STATISTICAL INFORMATION

Statistical information on germanium production and consumption is inadequate to provide an accurate industrial survey. Information available is published in the "Minor Metals" chapter of the Bureau of Mines Minerals Yearbook. The Business and Defense Administration of the U.S. Department of Commerce publishes quarterly reports on shipments and value of electrical components including those incorporating germanium. The Bureau of the Census, U.S. Department of Commerce, provides statistics on imports of germanium in concentrates and as dioxide and metal.

PRODUCTION, CONSUMPTION, AND TRADE

Germanium production has increased rapidly since 1948, and free world shipments were well over 200,000 pounds in 1962 including scrap returned for reprocessing and reshipment as well as primary material. The increased production along with significant advances in manufacturing efficiencies has resulted in an excess of domestic and foreign production capacity.

In 1963 an estimated 20,000 pounds of primary germanium was consumed in the United States, with total consumption of primary plus reprocessed scrap about 45,000 pounds. The number of semiconductor devices using germanium has shown a remarkable growth in re-

cent years. U.S. factory shipments of semiconductor devices using germanium advanced from 218 million units in 1960 to 547 million during 1963. Value, however, declined from $254 million in 1960 to $209 million in 1963. The increased efficiency of utilization and manufacture as well as price reductions for germanium metal are indicated in the greatly reduced unit value.

U.S. production of primary germanium has been augmented by imports of germanium in base metal concentrates from South-West Africa as well as germanium concentrates for refining. Imports of germanium metal and germanium dioxide, principally from Belgium and West Germany, amounted to 30,748 pounds valued at almost $2 million in 1961 but declined to 5,000 pounds valued at $284,000 during 1963.

The rate of duty effective under the revised tariff schedule of August 31, 1963, and the General Agreement on Tariffs and Trade is 10.5 percent ad valorum for germanium as dioxide and as unwrought metal.

PRICES

Price quotation for germanium ingots or cut ingots is normally based on the metric system of grams and kilograms. The most generally accepted standard measurement of purity and price basing is resistivity, made by using a two- or four-point probe on an abraded surface at 25° C. Polycrystalline ingot germanium, as reduced, has a resistivity in the range of 5 ohms per centimeter (minimum). This quality was quoted at 25.20 cents per gram in 10-kilogram lots, delivered to buyers' works, at the close of 1963. Intrinsic or ultra-high-purity polycrystalline germanium (minimum resistance of 40 ohms per centimeter) was priced slightly higher. Single-crystal germanium was quoted at 56 cents per gram, approximately twice the price of polycrystalline material. High-purity germanium dioxide (65 percent GeO_2) was quoted at 15.1 cents per gram approximately one-half the price of polycrystalline metal.

TAXES

The depletion allowance for germanium is 15 percent, domestic and foreign.

RESEARCH

Large-scale research on germanium was focused first on removing the element from zinc concentrates and later on the development of a process for refining the extracted germanium on a commercial basis. When this had been accomplished, the attention of the research program was directed toward finding industrial applications for the metal.

The search for significant industrial applications was successful in introducing the germanium diode during World War II. The transistor developed in 1948 by W. Shockley, J. Bardeen, and W. Brattain at the Bell Telephone Laboratory provided a major advance for germanium. These men received the Nobel Prize for their significant contribution to knowledge of solid-state physics which revolutionized electronic theory and design.

Intensive research conducted on the commercial recovery of germanium from coals and other hydrocarbons has not yet resulted in a competitive process. The large potential existing in this area, however, continues to provide an incentive for continued research (*7*, *8*, *10*).

A Germanium Research Committee was formed in 1959 by six domestic and foreign producers. The purpose of this group is to unite their research efforts to develop new uses for germanium and to disseminate information on germanium and its applications. Research being sponsored by the group is conducted by many research organizations throughout the world (*5*).

OUTLOOK

Semiconductor devices will continue to be the predominant use of germanium. There is a possibility that germanium in these devices may be replaced by materials that are less costly or more efficient or that have better thermal stability. Various alternate materials, principally silicon, have been developed, but for the most part they have found specialized or new applications rather than displacing germanium.

Although use of semiconductors is expected to increase substantially, germanium consumption will rise only moderately owing to the increasing efficiency of manufacture and utilization and some replacement by alternate materials.

The ready availability of germanium has spurred research in other applications such as specialized optical equipment, gages, precision casting alloys, storage battery electrolytes, and chemical catalysts. Significant promise for some applications could result in greater diversification and consumption. Germanium consumption in the United States in all uses could double from the estimated 20,000 pounds of new production in 1963 to 50,000 pounds within the next 10 years, and the free world demand, prin-

cipally in Japan, West Germany, and the United States, could increase some 50 percent to 150,000 pounds annually.

The world supply of germanium metal and compounds should be ample to meet foreseeable demand in current industrial applications for the next 10 years, provided the African countries that constitute the major free world source are politically and economically stable. Primary germanium for domestic use will be supplied by domestic zinc smelter fume, imported concentrates, refined metal, and compounds. It is unlikely that recovery of germanium from domestic zinc-mining operations will rise, therefore, any increase in requirements will be met by imports originating at central and south African base-metal mines.

Flue dusts and residues from metallurgical operations other than zinc plants and coal ash derived from plants burning high-germanium coals are potential domestic sources, but it is doubtful that competitive commercial methods will be developed in the near future under the anticipated level of demand.

PROBLEMS

The major problem facing the germanium industry is the lack of diversified industrial application for the element. While the semiconductor industry has provided the incentive for past research and production expansion, the future of germanium in this industry is uncertain. Research must be emphasized to overcome certain problems existing in manufacture, to develop new and diverse applications that will utilize significant quantities, and to assist in industrial adaptation of research findings.

Domestic germanium output is dependent upon zinc production. Coals and flue dusts of other metallurgical operations have not been utilized as sources of germanium because of problems concerning methods of economic recovery and evaluation of potential source material and future markets.

The lack of comprehensive resource information and statistical data pertaining to world production, shipments, consumption, and stocks of germanium is a handicap in the evaluation of the industry.

GOLD

By J. Patrick Ryan [1]

GOLD was one of the first metals used by man and has been prized because of its beauty, scarcity, and imperishability. Because of these qualities it has been widely used as a medium of exchange and a measure of value in world commerce. The use of gold in the arts and industries has increased in recent years as its special properties have led to applications in modern science and technology.

Total world production of gold from 1493 to 1963 is estimated at 2,216 million troy ounces, about 14 percent of which was produced in the United States. The United States was the leading gold producer of the world from 1849, the year after gold was discovered in California, until 1905, and in recent years has ranked fourth after the Republic of South Africa, Canada, and the U.S.S.R. The estimated world production of gold in 1963, 44.3 million ounces, was valued at $1,550 million—an alltime record.

Governments and central banks use most of the world's gold production to provide monetary stability for paper currencies and to settle international trade balances. A moderate quantity of gold is used in the arts and industry, and a substantial part of gold production is hoarded and held as an investment. At the end of 1963, the estimated free world monetary gold reserve was $42,285 million, about 37 percent of which was held by the United States.

The official U.S. price of gold has been $35 per ounce since 1934.

The reserve of gold-bearing ores in the United States was estimated at 20 million ounces in 1963, less than one-third of the 1944 reserve. This reserve is adequate to maintain output near the 1963 level for several years at current price-cost conditions. Consumption of gold has increased in recent years, especially in industrial and defense applications; in 1963 nearly 3 million ounces, or about twice domestic production, was used in the arts and industries of the United States. The deficit in new supply was balanced by withdrawals from the Treasury reserve.

BACKGROUND

Early methods of mining gold were primitive and production was small. World output increased rapidly after 1700 as deposits in the U.S.S.R. and South America were more extensively exploited and new deposits were discovered and developed in North America. The Southern Appalachian States began to produce gold in the early 1800's, but the output furnished only a small part of the world gold supply. After the discovery of gold placers in California (1848) and later deposits elsewhere, the United States became the leading world gold producer for more than half a century (*14*).[2]

Since 1905 the Republic of South Africa has been the leading gold-producing country. Three nations have ranked second, the United States (until 1930), Canada, and (probably) the U.S.S.R. (after 1934). Despite an increasing yield of byproduct gold from base-metal mining, the trend in domestic gold production was generally downward after 1915, recovering strongly after the price of gold was raised from $20.67 an ounce to $35 in 1934. Production reached an alltime high in 1940, dropped sharply during World War II, and had risen to one-half the prewar output by 1950. Since 1950 gold production has declined, and in 1963 it reached the lowest peacetime level in more than 100 years.

[1] Commodity specialist.

[2] Italicized numbers in parentheses refer to items in the list of references at the end of this chapter.

SIZE, ORGANIZATION, AND GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

In 1963 domestic production of gold was 1.45 million ounces, of which 13 percent was recovered by placer mining, 51 percent from gold and gold-silver ores, and 36 percent as a byproduct of base-metal ore. About 1,063 lode and placer mines were active and employed approximately 5,200 persons. The bulk of byproduct gold came from large-tonnage copper mines treating low-grade ore.

In 1963 of the 25 leading U.S. gold producers, 4 were lode gold mines, 5 were placers worked by bucketline dredges, 10 were copper mines, 3 were lead-zinc mines, 2 were copper-lead-zinc mines, and 1 was a zinc mine. These mines supplied about 94 percent of the domestic output valued at $50.9 million.

Gold is found in some quantity in nearly every country. In recent years gold has been produced in 75 countries. In the United States gold has been mined in 25 States, the principal ones in order of total recorded output being California, Colorado, South Dakota, Alaska, Nevada, Montana, and Utah. In order of current production they are South Dakota, Utah, Arizona, Alaska, Nevada, Washington, California, and Colorado. Current output from Utah and Arizona is almost entirely as a byproduct of base-metal ores.

The Republic of South Africa, the leading gold-producing country since 1905, supplied about 53 percent of world output in 1963. The U.S.S.R. probably has been second in gold production since 1934; Canada ranks third, supplying about 8 percent; and the United States is fourth, furnishing about 3 percent of the world output.

With few exceptions, domestic lode gold deposits are relatively small, widely scattered, and low grade. The Homestake mine in Lawrence County, S. Dak., the Nation's leading gold producer, treated about 1.9 million tons of ore in 1963—about 5,200 tons per day, by amalgamation and cyanidation. The Utah Copper mine at Bingham, Utah, the second largest gold producer, recovers gold as a byproduct of treating copper ore; about 26 million tons of ore, containing about 35 cents per ton in gold, was treated at this mine in 1963. These two mines produced nearly 57 percent of the total domestic output of gold in 1963. Nearly all of the U.S. placer mine production currently comes from Alaska and California and is recovered chiefly by bucketline dredging. In 1963, bucketline dredges treated 18.4 million cubic yards of gravel, averaging 31 cents per cubic yard in recoverable gold.

DEFINITION OF TERMS, GRADES, AND SPECIFICATIONS

According to the classification of ores adopted on the basis of smelter terminology, smelter settlement contracts, and metal recovery, gold, gold-silver, and silver ores with the base metal content too small to be classified as either copper, lead, or zinc ores are classified as dry ore regardless of the ratio of concentration. The dry ores are chiefly siliceous, valuable for their silver and gold content and in some instances for their fluxing properties, regardless of method of treatment. Dry gold ores are defined as those in which the gold value equals or exceeds three-fourths of the combined gold and silver values; dry silver ores are those in which the silver value equals or exceeds three-fourths of the combined gold and silver values. Dry gold-silver ores are defined as those in which both the gold and silver values equal or exceed one-fourth of the combined gold and silver values. Tailings and slags follow the same scheme of classification as ores.

The classifications are not to be modified by considerations of payments of metals by smelters or custom mills or by method of treatment by the smelters. Payments for gold are made on the basis of the troy ounce, 1,000 fine, at the official U.S. Treasury price of $35 per ounce.

The troy ounce, the basic unit of measuring gold and silver, may be defined as equivalent to 20 pennyweight or 480 grains. It is about 10 percent heavier than the common avoirdupois ounce. There are 14.583 ounces troy in an avoirdupois pound. It has become almost universal practice to weigh gold in troy ounces and decimal parts of an ounce or in pennyweights (dwts.) and decimal parts of a dwt. Fineness defines the proportion of pure gold in bullion or coin expressed in parts per thousand. Thus, fine gold is 100 percent pure, 1000/1000 fine. U.S. gold or silver coin is nine-tenths or 900 fine.

The term "karat" means a 24th part and is used to express the weight proportion of fine gold in an alloy; thus, pure gold is 24 kt; 18 kt alloy contains 18/24 or 75 percent gold. U.S. regulations require that a karat gold article of jewelry must be at least 10 karat or 416 fine. A tolerance of one-half karat is permissible. "Rolled gold plate" or "gold filled" are terms referring to articles made of base metal on which karat gold has been joined by soldering, brazing, or mechanical means.

Karat golds are made in red, yellow, green, and white as standard colors. The colored golds are basically ternary alloys of gold, silver, and copper. Zinc and nickel are also added to some jewelry karat golds. White golds are generally

composed of gold, copper, zinc, and nickel. Yellow golds are generally alloys of gold and copper containing some silver and zinc. Green gold is chiefly gold and silver containing some copper and very little zinc.

TECHNOLOGY

Geology

Gold deposits are found in many types of rock and in formations of all geological ages, but most of the productive deposits are associated with rocks of very early or of comparatively recent age. Nearly all gold-bearing deposits occur near acidic igneous intrusions, with which they show genetic relationship (*5*). The general deposit types include magmatic, contact metamorphic, replacement (lode, massive, and disseminated), and cavity filling (fissures, stockwork, saddle reef, breccia, and conglomerates). Gold, associated base metals, and gangue minerals occur in primary deposits in many combinations. Weathering and erosion cause gold in the free or metallic form to be released from primary deposits and to accumulate as nuggets and grains, forming residual or stream placers. Although the richest lode gold deposits have probably been found in small fissure veins with predominant quartz gangue, much larger quantities of gold have been mined from large, moderate-to-low-grade deposits.

Lode Mining

Methods of mining gold ore vary considerably from one mine to another and are based principally on such factors as size and shape of the ore bodies, physical and mineralogical character of the ore and surrounding rock, and depth of mining. The overall objective is to extract the maximum quantity of ore at the lowest cost consistent with safety.

The Homestake, the only large gold mine operating in the United States, is being mined through 3 operating shafts on some 30 levels, from the 1,400- to the 6,200-foot level. More than 200 miles of development workings consisting of drifts and crosscuts have been driven to provide access between shafts and ore bodies and to reveal the location and form of the ore bodies on successive levels. Shrinkage stoping, with square-set stoping of pillars, used for many years at Homestake to remove ore between levels, has been almost entirely superseded in recent years by open cut-and-fill stoping, as the mine became deeper and rock pressures increased. At present cut-and-fill stoping is providing better ore extraction and has proved safer and less expensive than other stoping methods. Crosscuts 7 by 7 feet in cross section are driven from development drifts at 200-foot intervals; raises 5 by 7 feet in cross section are driven from the crosscuts through the ore to the level above; and mining is begun in the raises at the bottom of the ore. A cut 18 feet high is mined as far out from the raise as the ore extends, and the broken ore is slushed into the raise, loaded into cars, and transported to the surface. When a stoping cycle is completed the two-compartment chimney, which is built into the raise, is carried to within 7 feet of the stope back, and the open stope is then filled with sand to the top of the chimney. After the plank floor is laid on the fill, the stope is ready for mining again. When the stope is mined up to the next level and breaks through into the crosscut, it is mined up 18 feet above the track level. A timberline is installed on top of the sand and covered with sand; it then serves as a haulageway for removing the ore up to the next level. The length that a cut-and-fill stope can be mined depends on the width of the ore body. Some stopes that are not over 60 feet in width have been mined 400 feet in length.

Milling and Treatment

Lode gold is recovered by cyanidation, amalgamation, flotation, gravity concentration, and smelting or by a combination of these processes. Metallurgical recoveries are high, sometimes exceeding 95 percent (*4*). Some mills recover a gravity or flotation concentrate that is treated by amalgamation and/or cyanidation, sometimes preceded by roasting. The concentrate may be shipped to a custom mill or base metal smelter, thus saving outlay for plant. All types of gold ore may be treated by direct smelting. Smelters may pay for siliceous or basic ingredients for their fluxing qualities.

Some of the early gravity concentrating devices used to recover gold, including blanket strakes, various shaking tables, and jigs, are still used at some plants. In the past 20 years the fundamentals of gold-mining practice and types of equipment used have changed little, but machine design and techniques have been greatly improved. Outstanding developments have been principally in crushing, grinding, and classifying; in applying flotation to certain ores; and in improving precipitation and roasting techniques. The adoption of hydrocyclones for classifying, thickening, and concentrating; fluid-bed roasting; and carbon cyanidation has increased operating efficiency and lowered costs.

At the ore-treatment plants of the Homestake Mining Co., approximately 70 percent

of the gold is recovered by amalgamation and 27 percent by cyanidation. The crushed ore from the gyratory crushers is reduced to about 70 percent through 200-mesh by two-stage grinding, using rod mills in open circuit and ball mills in closed circuit with rake classifiers. One grinding circuit uses a ball mill and cyclones. The pulp from the ball mills passes over amalgamators, which recover the major part of the gold in the form of amalgam. Rake classifier overflow is separated into sands and slimes in bowl classifiers and treated by cyanidation in separate sand and slime leaching plants. Sand leaching in vats by gravity percolation recovers about 18 percent of the gold produced. Slime leaching under pressure in filter presses recovers about 9 percent of the total gold. The gold in the cyanide solutions is recovered in the precipitation units by adding zinc dust, and the resulting precipitate is smelted to produce crude bullion. The amalgam is retorted in retort furnaces; the gold residue remaining and the crude bullion from the precipitate are melted and treated by chlorination; and the refined product is poured into 35-pound gold bars.

Several machines and techniques first used by the gold-mining industry have found widespread use in treating other ores. Agitation by mechanical and compressed air methods, slime thickening and washing, and continuous vacuum filtration have been adopted by many industries that handle finely divided solids in liquids—sewage treatment, water purification, and many wet chemical processes.

Placer Mining

Gold placer-mining comprises the work of excavating and delivering auriferous gravel to a washing plant for recovering the gold it contains (*1*, *7*, *8*, *9*). Placer gravel is excavated and fed to the washing plant by small-scale hand methods and by mechanical or hydraulic equipment. Gravel deposits, particularly those not adapted to bucketline dredging, are mined with dragline excavators and treated in nearby washing plants. Buried placers, too deep for stripping, are mined underground. Gold is recovered as a byproduct at several plants that produce building sand and gravel from streams. Floating dredges, combining the digging, washing, and tailings-disposal plants in one self-contained unit, handle 12,000 cubic yards or more of gravel a day.

Placer-mining recovery methods are based largely on gravity concentration and amalgamation. The basic device usually employed is some form of sluice, over which a stream of water washes the gravel. Mercury is often placed in the riffles. Undercurrents are sometimes employed in wide sluices through which very fine gold particles may pass to an undersection; matting, carpet, corduroy, or small-size riffles catch the gold. Jigs may supplement or be used in place of tables. Gold is recovered from the heavy sand concentrate in amalgamating barrels. Recovery of coarse and moderately fine gold may exceed 90 percent, but that of fine or "flour" gold is low, particularly when clay is present in quantity.

Dry placer concentration processes, using air pulsations instead of water, have been developed in some areas in the Southwest (*7*).

Byproduct gold from domestic base metal ores is recovered as gold bullion at base metal refineries (*15*). Losses of gold in concentrating are about the same as those of the base metal but are negligible in smelting.

Gold is refined by chlorination in the molten state (Miller process) and by electrolysis (Wohlwill process). The latter process, used by the U.S. mints, gives a final bullion product 999.5 to 999.8 fine.

USES

Most of world gold production is absorbed by governments and central banks to provide stability for paper currencies and to settle international trade balances, but in recent years large quantities of gold have gone into private holdings. The chief nonmonetary uses of gold are in jewelry and the decorative arts, including watchcases, utensils, gold leaf, and decorative finishes on ceramics and other materials. Gold in various alloys with platinum-group metals is used in dentistry, for spinnerets in making synthetic fibers, thermocouples and electrical contacts, and in many types of scientific laboratory equipment. Gold also continues to find new applications in industry, particularly as protective and decorative coatings for other materials, and in recent years as coatings on ceramics and metals in architectural panels, as coatings on aircraft engine shrouds and earth satellites to provide protection against heat and corrosion, and for electrical components and circuitry where extreme reliability is required. Appreciable quantities of gold are consumed in established uses in the fields of optics, atomic energy, heat control and measurement, medical therapy, chemical manufacturing, and brazing.

BYPRODUCTS AND COPRODUCT RELATIONSHIPS

Silver, always associated with gold to some degree in nature, is a coproduct of all gold mining; the average ratio by weight is about

1 part silver to 4 of gold. Crude platinum, sometimes present in gold placers, is recovered as a byproduct; in some areas in Colombia enough platinum is present that it becomes a coproduct. Platinum-group metals also occur in some lode gold ores. In the final refining of gold in the United States, a few thousand ounces of platinum-group metals are recovered annually.

The average recoveries of gold per ton from all base metal ores from which gold was recovered in 1963 were copper ore, $0.11; lead ore, $0.46; zinc ore, $0.07; and zinc-lead-copper ore, $0.56.

Uranium is recovered as a byproduct or coproduct of gold ores at several mines on the Rand in the Republic of South Africa and is a major source of revenue at some mines. From 5,000 to 7,000 ounces of osmiridium also are recovered annually as a byproduct of the Rand gold ores.

ALTERNATE MATERIALS

Alloys of the platinum-group metals such as platinum-iridium and palladium-ruthenium are substituted for gold in high-quality jewelry, watchcases, and other decorative articles, their use being determined largely by popular demand and vogue. The various metals and their use in place of gold include platinum and palladium separately or alloyed with gold for various appliances in dentistry; platinum leaf (for gold leaf) for signs and decorative designs; and stainless steel, chromium, and nickel alloys, in corrosion-resistant equipment. The quantity of gold displaced by substitution of other materials is small, however, compared with the consumption of gold in the arts and industry.

SECONDARY SOURCES

Because of the indestructibility and high value of gold, there is a high return from old jewelry, watchcases, optical frames, dental crowns, and laboratory ware. The secondary metal recovered by refiners can be of the same high quality as primary metal. According to the Bureau of the Mint, scrap gold returned from industry annually averaged about 950,000 ounces during 1959–63.

RESERVES

A preliminary estimate of domestic gold reserves, based on data compiled in a current study of the Nation's gold potential, shows a total of 20 million ounces of gold, virtually all of which is recoverable under current economic and technologic conditions. This reserve comprises 1 million ounces in placers, 5 million ounces in lode gold ores, and 14 million ounces in base-metal ores, mostly in large low-grade copper ores.

The current estimate of domestic gold reserves is based on a reserve study made in 1944 (*3*) with allowance made for subsequent production, new discoveries, and losses due to increased production costs.

One substantial new discovery in Nevada is expected to produce about 1 million ounces. New discoveries and favorable economic conditions have resulted in an increase of 15 million ounces in the estimated recoverable byproduct gold from base-metal ores. It is estimated that byproduct gold production will continue at the present rate for 30 years. The unfavorable economics of placer and lode gold mines is significant—dredges in California will exhaust economically minable gravel in less than 5 years. The profit margin at the Nation's major lode producer has declined to a low level, and unless the decline is arrested operations might be terminated in 5 years.

Reliable data on gold reserves in many countries are nonexistent or unavailable. Gold reserves in the Republic of South Africa are estimated to total more than 500 million ounces of which about 90 million ounces is in fully developed ore blocked out at the end of 1963. An additional 4 million ounces is contained in pillars and dumps, most of which may ultimately be recovered. Reserves of gold in ore and placer deposits in the U.S.S.R. are believed to be large; some significant new discoveries have been reported but detailed data are not available. In recent years increases in gold reserves resulting from new ore discoveries and extensions of known ore deposits, particularly in South Africa, have helped to offset declines in other principal gold-producing countries. The world reserve of recoverable gold may approximate 1 billion ounces, with about 75 percent in gold ores and placers and 25 percent in base metal ores.

Although gold is present in only minute unit quantity in sea water and the problem of extraction is unsolved, analytical experiments indicate that a cubic mile of sea water contains 130 to 260 tons of gold, equivalent to 3.8 to 7.6 million ounces.

Monetary gold reserves of the principal free world central banks and governments and international banking institutions at the end of 1963 aggregated $42.3 billion (*6*). It is estimated that an additional $15 billion in gold is held in private stocks. Estimates of the gold reserve of the U.S.S.R. range from about $1.8 billion to $10 billion.

The U.S. gold reserve of about $15.6 billion at the end of 1963 constituted about 37 percent of the total official reserves of the free world.

Gold reserves of other principal free world countries, in billions of dollars, at the end of 1963 were West Germany, 3.8; France, 3.2; Switzerland, 2.8; United Kingdom, 2.5; Italy, 2.3; Netherlands, 1.6; Belgium, 1.4; and Canada, 0.8. The International Monetary Fund reported gold reserves of $2.3 billion.

SOURCES OF STATISTICAL INFORMATION

In the United States, statistics on the domestic mine production of gold are gathered, analyzed, and compiled by the Bureau of Mines in cooperation with the geological surveys of some States. Monthly and annual reports are published. Data on refinery production and on domestic and foreign consumption in the arts and industries and coinage are compiled and published by the Bureau of the Mint, U.S. Treasury Department. Data on consumption of gold by principal industrial uses are compiled semiannually by the Office of Gold and Silver Operations, U.S. Treasury Department. Foreign trade data on gold ore and bullion are published by the U.S. Department of Commerce. Comprehensive data on gold transactions of the free world countries and international institutions, including net gold purchases and estimated gold reserves of central banks and governments, are compiled and published monthly by the Board of Governors of the Federal Reserve System. Monthly bulletins of the U.S. Treasury Department publish detailed data on U.S. monetary gold stocks and banking transactions related to gold.

The Bureau of Mines also compiles data on gold production in foreign countries. Detailed data on gold production are published by some foreign countries, especially those of the British Commonwealth, but corresponding data for other countries are not complete. No data on gold production or reserves are published by the U.S.S.R. or the other Communist nations.

PRODUCTION, CONSUMPTION, AND TRADE

The total world gold production from 1493 to 1963 is estimated at 2,118 million troy ounces. Peak annual production prior to World War II was 42.2 million ounces in 1940. Since World War II, world gold production has steadily increased, reaching a total of 44.3 million ounces valued at $1.55 billion in 1963 (fig. 1). The gain in world output was due principally to the remarkable growth in gold mining in the Republic of South Africa. In recent years the United States has ranked fourth in gold production, exceeded by the Republic of South Africa, Canada, and the U.S.S.R. In 1963 U.S. production (fig. 2) was 1.45 million ounces; total output to the end of 1963 was 304.02 million ounces, or 14 percent of the world total since 1493.

Of the cumulative quantity of gold produced from the earth, it is estimated that 55 percent is held by governments and central banks, 30 percent is held by corporations and individuals, and 15 percent has been dissipated or lost.

During 1959–63 net consumption of gold by industry and the arts in the United States was nearly double domestic production. Estimated consumption of gold in the industries and arts of the principal free world countries in 1963 was about 9.3 million ounces; that used in coinage totaled 0.45 million ounces (*2*).

During 1963, the United States imported gold ore, base bullion, refined bullion, and gold coins from 23 countries and exported these items to 7 other countries. Refined bullion comprised the bulk of the imports and exports. In 1963 Canada supplied nearly one-half of the gold imports; Colombia and the Philippines supplied most of the remainder. Of the total gold exported in 1963, about 70 percent went to France and 28 percent to the United Kingdom. Prior to 1961 imports of gold greatly exceeded exports, but 1961–63 exports increased sharply, exceeding imports by a wide margin. The United States imposes no duties on gold imported in ores or bullion but does levy duties ranging from 30 to 65 percent ad valorem on manufactured goods. The volume of imports of such gold merchandise is relatively small, however.

STRATEGIC CONSIDERATIONS

Although there are not many industrial uses of gold that are indispensable to the military services, the U.S. gold reserve is strategic and important in maintaining fiscal solvency, since gold is the monetary base for currency and the standard for settlement of international trade balances.

The reserve of gold-bearing ores in the United States is enough to maintain production near the current rate for several years under a cost-price relationship near the present level. Moreover, domestic gold consumption in the arts and industry will probably continue to exceed production in the near future (table 1). The deficit in domestic supply will be balanced by sales from the Treasury stock; how-

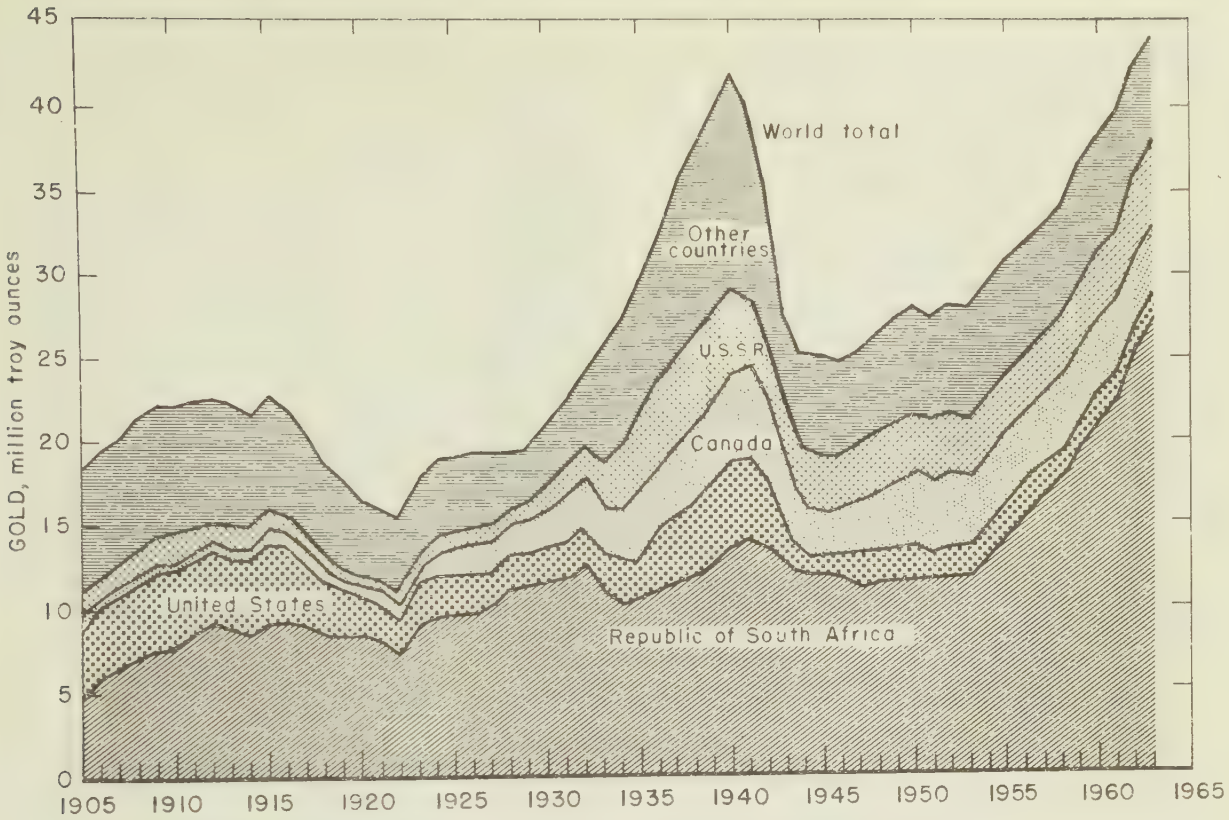

FIGURE 1.—World Gold Production.

ever, this stock is declining steadily as withdrawals are made in connection with settlement of adverse trade balances. Imports of gold into the United States are shown in table 2.

TABLE 1.—*Net industrial consumption of gold in the United States* [1]

[Thousand troy ounces]

Year	Issued for industrial use	Returned from industrial use	Net industrial consumption
1954–58 (average)	2,247	796	1,451
1959	3,176	654	2,522
1960	3,700	700	3,000
1961	3,913	1,138	2,775
1962	4,486	910	3,576
1963	4,252	1,332	2,920

GOVERNMENT PROGRAMS

The most far-reaching U.S. Government policy affecting gold is the establishment of the gold parity of the dollar. A firm policy of maintaining the $35 rate has been expressed

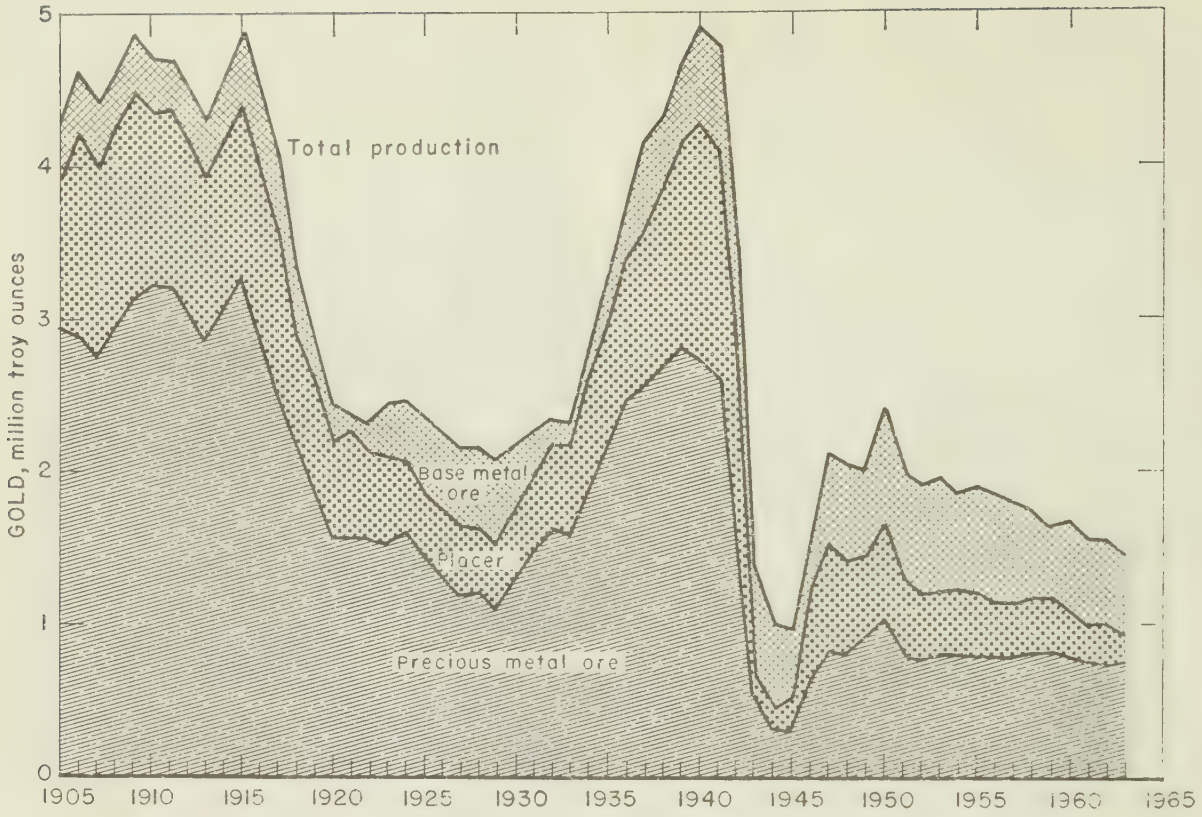

FIGURE 2.—U.S. Gold Production.

repeatedly since World War II. This price forms the basis for the official world price because the United States stands ready to purchase all gold offered at $35 per ounce.

The most recent statement of policy concerning the price of gold was made by President Johnson in his Economic Report to the Congress in January 1965.

> There can be no question of our capacity and determination to maintain the gold value of the dollar at $35 an ounce. The full resources of the Nation are pledged to that end.
>
> Clearly, we should place beyond any doubt our ability to use our gold to make good our pledge to maintain the gold value of the dollar at $35 an ounce with every resource at our command.

Transactions in gold are subject to government regulations that require gold bullion and gold coins to be delivered to U.S. Treasury institutions. Licenses are issued by the Treasury Department permitting purchases, sales, imports, and exports of gold for use in the arts and industries.

The government program of financial aid administered by the Office of Minerals Exploration provides for loans to explore gold deposits up to 50 percent of the total cost of such exploration. The loan is repaid by a 5-percent royalty on any production from the property.

Since 1948 the Canadian Government has granted financial assistance to marginal or high-cost gold mines under terms of the Emergency Gold Mining Assistance Act (EGMAA) to help them meet the greatly increased cost of production after World War II. The subsidy program under EGMAA was extended with certain amendments through 1967. Similar cost-aid subsidies in Australia and tax concessions in Australia and the Republic of South Africa have aided some marginal gold mines. Most foreign governments have permitted gold producers to benefit by selling part of their output at premium prices in the free market.

PRICES

After being $20.67+ per fine troy ounce for nearly a century, the price of gold was raised to $35 per ounce by Presidential proclamation in January 1934 and has remained unchanged since then. Presidential power to revalue gold lapsed in 1943; only an act of Congress can change the gold parity of the dollar. During and after World War II, hoarding in various parts of the world increased demand, and some gold was sold in free markets developed outside the United States; prices were substan-

tially higher than the official $35 per ounce. When restrictions on the sale of gold were relaxed by some foreign countries and by the International Monetary Fund (1951), part of the world production was sold at free market prices. The not always realistic higher prices in some of these markets reflect the difference between official and free market foreign exchange rates.

In 1963 the price of gold on the London exchange (where most of the gold trading is done) fluctuated in a narrow range close to the official U.S. price of $35 per ounce, owing principally to the stabilizing operations of the Bank of England on behalf of the international gold pool and the bank's handling of the sale of South African gold. In 1963 the price of bar gold in most world markets was only slightly higher than the London price, except in markets that reflected local trading and monetary habits and that used inconvertible currency.

Before gold was revaluated in 1934, world production at the former price, $20.67+ per ounce, had been declining for many years because of rising costs and depletion of ore reserves. Stimulated by the $35 price, gold mining again flourished and many countries set new production records in the late 1930's and early 1940's. During World War II gold mining declined in most countries because of restrictions, shortage of labor and supplies, and higher costs. In the postwar years steadily rising costs in relation to the fixed price of gold made several gold mines in the United States unprofitable. Most large lode gold mining companies of the world continued to mine their higher grade reserves profitably, but many small mines closed. Base-metal mines that yield byproduct gold were not greatly affected by the fixed price of gold because the increased price of base metals tended to offset the increased cost of mining.

TAXES

The gold mining industry in the United States generally is taxed the same as other industries. The depletion allowance for gold is 15 percent. Some countries impose a production or export tax on gold that may add to the mining cost; others promote gold mining by tax concessions.

RESEARCH

The processes of recovering gold from ores, particularly amalgamation and cyanidation, have attained high metallurgical efficiency owing to extended operating experience and research by commercial laboratories, manufacturers, and mining companies on chemical reagents, design of machinery, and procedures. Research is necessary to adapt the basic processes to the peculiarities of some ores and to meet special conditions, and such research is done by mining companies and ore-testing laboratories.

Recent investigations by the Canadian Mines Branch in cooperation with the gold mining industry have yielded useful results and have shown how metallurgical efficiency in treating some ores can be improved by the adoption of modern scientific techniques.

Fundamental studies of gold milling processes and possible automation of operations to increase productivity and to lower costs are constantly being studied by gold mining companies in many parts of the world.

Bureau of Mines basic research yields information that contributes to greater efficiency and safety in mining, better evaluation of mineral resources, and increased recovery of ores and metals from mineral deposits. These fundamental studies aid gold mining as well as other types of mining.

Research on the cyanidation and chloride volatilization of refractory gold ores was conducted by the Bureau during 1918–28; the carbon-cyanidation treatment of gold ores proved commercially feasible in more recent investigations (*19*). Recent metallurgical research by the Bureau included applying ultrasonic principles to amalgamation and cyanidation to improve efficiency and recovery of gold.

OUTLOOK

U.S. production of gold should hold fairly steady near the 1963 output in the next few years and then decline slowly as production costs continue to rise and economically minable reserves at gold mines gradually become depleted. New production in Nevada will probably offset decreased production in other areas in the near future. Byproduct gold production from base-metal mines probably will continue at about the current level.

The rising trend in world gold production should continue in the next few years as output from South Africa, which constitutes more than one-half of world production, continues to grow. Continued expansion of output at new mines in the Orange Free State and in the Far East and Far West Rand areas in the Transvaal will be offset to some extent by a falloff in production in the Central Rand owing to depletion of economically minable reserves at some of the older

780-887 O—65——26

mines. Although South African gold production has been rising for the past 12 years and establishing record highs, it is believed that output is approaching a maximum level and will probably begin to decline within the next decade. The gold mining industry in South Africa accounts for about 45 percent of the country's exports and receives substantial financial assistance from the Government, principally in the form of loans, tax concessions, and amortization allowances. Gold production in Ghana has been rising in the last few years reaching an alltime record in 1963, but output in Canada and Australia has been slowly declining, in spite of subsidies and other forms of Government aid to the gold mining industry.

Although gold is used primarily as a monetary reserve of government central banks to stabilize currency and to settle international trade balances, world authorities disagree on requirements for monetary gold. Anticipated additions to the gold reserves of free world countries will depend chiefly on such factors as new production, gold sales by the U.S.S.R., demand for gold in the arts and industries, demand for private investment, and hoarding. In recent years more than half of the new gold production was absorbed by private interests. Official gold stocks have increased by only 1.3 percent annually over the past 15 years owing to sustained private demand. Operations of the gold pool supplemented by sales from the U.S.S.R. will continue to be principal factors in providing sufficient gold to meet all demands and in maintaining a stable price in world markets.

Consumption in domestic industries and the arts has been increasing, largely owing to increased use of gold in modern science and technology. New applications in industry and in defense-oriented equipment will continue to be developed, based essentially on gold's superior malleability, ductility, resistance to tarnish, and high reflectivity. The growing use of gold as a protective coating on other, less-resistant materials is significant. These coatings, which are sprayed or electrodeposited, provide oxidation resistance on space vehicles and in electrical components as well as providing decorative and corrosion-resistant finishes on a wide variety of commercial products.

Investigations being conducted by the Committee for Research on the Properties and Uses of Gold, Inc., may lead to increased industrial use of gold as new applications are developed. Growth of established, traditional uses of gold in jewelry and the decorative arts will probably parallel the growth in gross national product and population.

Although advances in science and technology may lead to new and improved prospecting techniques, new sources of gold will be discovered less frequently, as economic conditions in the industry become progressively less favorable and incentive for prospecting and exploration for gold continues to decline. Some new sources probably will be discovered in South Africa, the U.S.S.R., and Canada, but no significant new discoveries can be expected in the United States under present economic conditions.

It is difficult to forecast the quantity of gold required annually to meet monetary requirements and to provide reserves adequate for international liquidity. Some authorities believe that the monetary reserves of the free world are too low in purchasing power to provide full mobility for trade and capital. The U.S. gold reserve has been declining in recent years and those of Western Europe have been increasing as a result of balance-of-payments transactions. However, the high rate of outflow of gold from the U.S. reserve may have been arrested in the past 2 years as the U.S. balance-of-payments position shows signs of improving and stabilizing operations of the International Monetary Fund and the International Gold Pool become more effective.

PROBLEMS

The paramount problem facing the domestic gold mining industry is one of survival in the face of rising costs and a fixed price of its product. This pattern has resulted in closing most of the gold mines in the United States, and has been repeated throughout the world. In all places except South Africa and possibly Ghana, it has resulted in reduced profits, loss of ore reserves, and depression in the gold mining industry. Revaluation of gold in terms of dollars, or a substantial reduction in the cost of production, could revive the industry. However, fixing the price of gold in the Nation is mainly a monetary rather than a commodity problem.

The problem of rising costs due principally to the effect of inflationary factors has been partly offset at some mines by technological improvements and operating economics; however, further savings in the foreseeable future appear unlikely and reserves of minable ore at the relatively few operating mines remaining will probably diminish unless there is some unforeseen change in production cost or the price of gold.

The resource base of the domestic gold mining industry has been depleted by more than 100

years of intensive exploitation, when most of the high-grade, easily accessible ore was mined. The industry's problems were intensified by the closing of mines in World War II and subsequent high cost of rehabilitation. Many mines that were operating prior to the closing order were unable to restore production when the order was rescinded.

Other basic problems are related to the small size and wide distribution of many deposits. The vein-type source and ground conditions of most gold mines preclude the use of large-scale equipment successful in reducing costs in base metal mines.

Consumption of gold in the domestic arts and industries has exceeded mine production since 1957, and the deficit in new supply is increasing as production continues to decline. Hence, a long-term domestic gold problem is to find and develop new supply sources to balance the growing industrial demand.

Many technologic problems of gold mining are common to other underground mining operations—basically they are cost problems inherent in breaking hard siliceous rock sometimes deep within the earth's crust, transporting it to milling and processing plants, and extracting minute quantities of contained gold.

Deficiencies exist in statistics on industrial consumption of gold, which are needed by producing and consuming industries and by government in formulating policy, assessing trends, and estimating future demand. Data on end use and quantities used in various industries are incomplete or totally lacking, and this deficiency is a serious handicap in developing a comprehensive program for gold.

Problems of monetary reserves and liquidity are concerned chiefly with supplying the gold required for expanding world trade and involve international political and financial policies.

GRAPHITE

By John W. Cole [1]

GRAPHITE mining in the United States always has been a small scale industry, and significant expansion in production has occurred only in wartime under government subsidy. In 1963, domestic graphite was produced only in Texas. Foreign deposits occur over a wide area; those in the Malagasy Republic, Ceylon, and Mexico provide most of the graphite consumed in the United States.

The three major types of natural graphite are lump, amorphous, and flake. All three types are mined underground by conventional mining methods, although most flake graphite is mined by open pit methods. Hand cobbing and sorting are the major steps in preparing Ceylon lump graphite for market. Amorphous graphite requires only crushing or grinding to the desired particle size. Flake graphite must be concentrated and refined before marketing. Special grades of high-purity graphite are produced by chemical treatment.

Manufactured graphite is produced from petroleum coke by baking at about 950° C and subsequently graphitizing at about 2,800° C. Graphites with special properties, such as oriented and recrystallized types, are being developed for use in space-age applications and as more knowledge of them is obtained, their use is expected to grow.

Although some interchangeability is possible among all types of natural graphite and between natural and manufactured graphite, there is no satisfactory substitute for graphite in most applications. Silicon carbide-graphite crucibles have reduced the need for coarse-flake graphite, and some high-temperature refractory materials such as nitrides, borides, and silicides may be suitable replacements for clay-graphite crucibles requiring coarse-flake graphite.

Potential domestic resources of flake graphite are large but low in tenor. Amorphous graphite, although abundant in the United States, is of poor quality. World graphite resources of all types are enoromous.

The principal uses for natural graphite in 1963 were foundry facings (36 percent), steelmaking (16 percent), lubricants (14 percent), and refractories (11 percent). The use pattern varies widely for the major types of graphite.

Although the United States could achieve self-sufficiency in crystalline flake graphite, the cost would be two to three times the normal market price of Malagasy flake. Moreover, about 1,000 short tons a year of Ceylon 97 to 98-percent carbon amorphous lump would still be required for strategic uses. Stockpile objectives have been achieved for strategic and critical grades of natural graphite.

The short- and long-term supply outlook for all types of imported graphite required for the U.S. economy is favorable, and domestic production could be expanded if necessary. There is no indication of a major increase in requirements for natural graphite. Manufactured-graphite production facilities are adequate for present needs.

Problems of the natural graphite industry include the limited market for graphite of each type and the reluctance of consumers to use graphite from untried sources. Major technologic problems include determining the interchangeability possible among various types of graphite and increasing U.S. self-sufficiency. A major problem of the manufactured-graphite industry has been the inability to produce graphite to stringent specifications.

[1] Commodity specialist.

BACKGROUND

SIZE, ORGANIZATION, AND GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

From 1910 through 1963 the number of domestic graphite producing mines ranged from 42 (in 1918) to 1 (in 1932, 1940, 1962, and 1963), and annual production ranged from less than 500 to 13,600 short tons. Some domestic production has been reported every year since 1884, but apparent consumption has ranged from 5 to more than 15 times domestic production. The history of the domestic graphite-mining industry is thus reflected to have been one of short periods of production, under the stimulus of Government subsidy during wartime, to long periods of inactivity for most individual deposits.

Only one domestic producer continued to operate in 1963. Southwestern Graphite Co., Burnet, Tex., produced small-flake crystalline graphite from weathered graphite schist containing about 5 percent graphite, from an open pit mine.

Graphite recovered from milling the ore is sized and graded by carbon content into more than 20 different grades. Final products are shipped directly to consumers throughout the United States.

Graphite has been reported in 25 states in the United States, and 17 have produced it in commercial quantities (*1*).[2] Flake graphite has been mined in Alabama, California, Massachusetts, New Jersey, New York, Pennsylvania, and Texas. Amorphous graphite has been mined in Colorado, Georgia, Michigan, Nevada, New Mexico, North Carolina, Rhode Island, Utah, and Wisconsin. A small quantity of lump graphite has been mined near Dillon, Montana.

Graphite deposits occur in virtually all countries; the foreign deposits of most importance to the United States economy are the lump deposits of Ceylon, the amorphous deposits of Sonora, Mexico, and the crystalline flake deposits of the Malagasy Republic.

Mexican companies, some of them affiliated with U.S. firms, mine 80- to 93-percent carbon amorphous graphite from underground mines in Sonora, Mexico. Most of the output is exported to the United States. Ore is sorted into grades, crushed, and shipped in carlots to end-use customers or to U.S. plants for additional treatment.

Graphite is imported from the Malagasy Republic, Ceylon, Norway, West Germany and other foreign sources. Importers grind and blend graphite to consumer specifications. Manufactured graphite powder and shapes are produced by 5 firms in 10 plants: 3 are situated in New York, 2 in Pennsylvania, and 1 each in California, Michigan, North Carolina, Tennessee, and West Virginia.

DEFINITION OF TERMS, GRADES, AND SPECIFICATIONS

Graphite, a form of carbon that crystallizes in the hexagonal system, also has been referred to by industry and in publications as plumbago and black lead.

The three major types of natural graphite, based on geological occurrence, are lump (from vein deposits), amorphous (from metamorphosed coalbeds), and crystalline flake (from layered metamorphosed rocks).

The terms "amorphous" when applied to graphite is a misnomer; all graphite is crystalline, but the type designated as amorphous is so fine grained that individual crystals cannot be distinguished by the unaided eye. The definition of amorphous, as applied to graphite, has been further complicated by longstanding industrial application of the term to very fine particles of crystalline flake graphite that can be sold only for low-value uses, such as foundry facings, and its application to the fine-grained varieties of Ceylon lump graphite. These fine-grained varieties of lump can be reduced easily to fine particle size by grinding. They are called amorphous lump to distinguish them from tough, platy, and acicular varieties, known as crystalline lump, that can be reduced in particle size only with extreme difficulty.

Paragraph 213 of the Tariff Act of 1930 defines crystalline flake graphite as follows:

> As used in this paragraph, the term "crystalline flake" means graphite or plumbago, which occurs disseminated as a relatively thin flake throughout its containing rock, decomposed or not, and which may be or has been separated therefrom by ordinary crushing, pulverizing, screening, or mechanical concentration process, such flake being made up of a number of parallel laminae, which may be separated by mechanical means.

Under the foregoing definition finely divided particles of crystalline flake graphite would be classified as crystalline graphite. However, the

[2] Italicized numbers in parentheses refer to items in the list of references at the end of this chapter.

Court of Customs Appeals has repeatedly held that commercial designations and not scientific terms must govern classification and that when a commercial meaning differs from the common meaning the commercial designation must govern. Thus, large quantities of fine crystalline flake graphite are imported under the amorphous classification.

Ceylon lump graphite, as previously stated, is classified as amorphous or crystalline. Each type is divided into a number of grades, depending upon the particle size (lump, ranging from the size of walnuts to that of peas; chip, from the size of peas to about that of wheat grains; dust, from 40- to 60-mesh; and flying dust, finer than 60-mesh), graphitic carbon content, and degree of consolidation (*7*).

Amorphous graphite is graded primarily on graphitic carbon content. Commercial ores contain about 50 to 93 percent carbon, depending on their source.

Crystalline flake graphite from the Malagasy Republic is divided into two main grades, "flake" (coarse flake) and "fines" (fine flake). Malagasy crucible flake must have a minimum of 85 percent graphitic carbon and be essentially all minus 8- plus 60-mesh. Other crystalline flake graphites are graded according to graphitic carbon content and particle size.

The terms "manufactured," "artificial," "electric-furnace," and "synthetic" are used to describe graphite produced from coke.

TECHNOLOGY

Geology (*1*)

The classification of natural graphite into three principal types is based on physical characteristics that are due to major differences in geologic origin and occurrence.

Lump graphite occurs as fissure-filled veins. It is typically massive, ranging in particle size from extremely fine grains (amorphous) to coarse, platy intergrowths or fibrous to acicular aggregates (crystalline). The origin of vein-type graphite deposits is believed to be either hydrothermal or pneumatolytic. The veins cut different types of igneous and metamorphic rocks; apparently the nature of the host rock bears no genetic relationship to the veins. Minerals occurring as impurities with the graphite include feldspar, quartz, mica, pyroxene, zircon, rutile, apatite, and iron sulfides. These impurities usually form isolated pockets or grains in the veins.

Amorphous graphite is formed by metamorphism of coalbeds by nearby intrusives. The graphite from these altered coals is extremely fine grained, soft, dull, black, earthy-looking, and usually somewhat porous. Its purity depends on the purity of the original coalbeds. Amorphous graphite usually is associated with sandstones, shales, slates, and limestones. Accessory minerals include quartz, clay, and iron sulfides.

Flake graphite commonly occurs disseminated in regionally metamorphosed sedimentary rocks, such as gneisses, schists, and marbles. It is believed that the graphite was formed under the same conditions that caused the metamorphism of the rocks—from carbon deposited with the sediments.

Although the flake graphite deposits of the Malagasy Republic conform to this description, the commercial deposits that are exploited are alluvial, lateritic cover that has accumulated at the surface (*13*). The graphite, quartz, and other resistant minerals have been freed by kaolinization of the feldspars. Laterization extends to a depth of several meters. The grade of ore usually is 5 or 6 percent graphite.

Mining

In Ceylon, lump graphite is mined underground from narrow, steeply dipping veins. The ore is mined principally by overhand stoping and filling, using temporary stulls when necessary to support the walls. Hand drilling is used in most stoping to achieve selective mining and to avoid unwanted fines and product contamination. Air drills are used in development headings. Minor sorting is done at the mine on the surface. The ore is hauled by truck to the sorting and classification yard.

Amorphous graphite beds usually also are mined underground, but the beds are much thicker than those of amorphous and crystalline lump. The ore is drilled, blasted, hand-loaded in cars, and brought to the surface by conventional methods.

Flake graphite deposits have been mined by underground and surface methods. Usually underground deposits are in unweathered ore and require drilling and blasting. Most surface mining is confined to the weathered part of the deposit, and normal excavating equipment, such as power shovels, bulldozers, and scarifiers, is used with a minimum of drilling and blasting.

Mining at the property of the Southwestern Graphite Co. near Burnet, Tex., is conducted by open pit methods. Sixteen foot benches are drilled for blasting by use of wagondrills. The rock is hard and tough; much secondary blasting is required. The ore is hauled to the mill by use of motortrucks.

In the Malagasy Republic the graphite ore is transported by hydraulic methods. Water is

brought many miles by ditches and flumes to the top of the deposit selected for mining. The soft, weathered ore is fed by hand or bulldozers into the flowing water and carried by a flume or canal to a mill less than a mile away in the valley below. Overburden is removed in the same manner but bypassed around the mill. The swiftly flowing water not only transports the ore, but the resulting slaking and tumbling action breaks the clay-like material and serves as the first step in separating the graphite from the gangue.

Milling

Ceylon amorphous and crystalline lump graphites are refined by hand cobbing and sorting, and wiping lumps on wet burlap to remove fines. The chip and dust grades are machine-sorted in revolving trommels. Light hand sorting and cleaning operations are done by women while the heavier duties are performed by men.

Most amorphous graphite that requires concentrating is not worth mining. Preparation for most uses requires grinding only, and coarse impurities are removed by screening or air separation methods. Recently a new flotation plant was installed in Austria to upgrade microcrystalline graphite to a grade ranging from 80 to 92 percent carbon with a particle size range of 0.005 to 0.008 inch. This plant is reported to be the first flotation plant in the world to be successful in enriching microcrystalline (amorphous) graphite (*3*).

Flake graphite from disseminated deposits must be concentrated to meet market requirements. Virtually every known concentrating device and combination of separating principles have been tried. Probably in no other industry has such a large proportion of the mills failed to make commercial recoveries. Many so-called secret processes have been used to concentrate graphite, and the mineral has gained a reputation of being difficult to concentrate. Actually, it is one of the easiest minerals to segregate into a rough concentrate but one of the most difficult to refine.

As a premium is placed upon the grain size of flake graphite, the problem in milling is one of grinding to free the graphite without reducing the flake size excessively. This is difficult because graphite flake during grinding is cut by quartz and other sharp minerals in the gangue, thus reducing flake size rapidly. However, if the flake can be removed from most of the quartz and other sharp minerals soon enough, subsequent grinding will usually reduce the size of the remaining gangue, with little further reduction in the size of the flake. Impact grinding of essentially pure flake in a ball mill reduces flake size rather slowly. The grinding characteristics of flake graphite under these conditions are similar to those of mica.

Graphite is a natural floater and does not require a collector; hence flotation has become the accepted method for beneficiating disseminated ores. High recoveries are common, but acceptable graphitic carbon contents are difficult to attain. The main problem in separation is to depress the gangue. Fine graphite smeared on the surfaces of relatively pure particles of quartz, mica, and other gangue minerals makes them floatable, necessitating repeated cleaning to permit recovery of high-grade products.

Regrinding a rougher concentrate reduces the number of cleanings needed. The difficulty in obtaining high-purity products from natural flake stems from the fact that much of the flake either has a siliceous skeleton (which can be seen when the carbon is burned) or is composed of a layer of mica between outer layers of graphite. Sometimes it is impossible to obtain high-grade material.

In the Malagasy Republic (*13*) graphite ore from the flume or canal flows over a screen or grizzly with 5 to 10 mm spacing. Oversize is discarded. Undersize passes through a decantation tank. The mud overflows while graphite and sand settle to the bottom. Graphite in the mud is recovered by washing on 60 to 80 mesh screens. Mud is washed through the screen and the graphite and sand is discharged from the top. Graphite is recovered from the sand by flotation. A crude graphite product containing 65 to 80 percent carbon is recovered from the washing plant at the mine. This product is shipped to a central refining plant where it is ground in ball or rod mills, refloated, screened, and blended into specification grades. The final products are plus-60 mesh flake containing 85.0 to 87.5 percent graphitic carbon, and minus-60 mesh material that contains 90.0 to 92.5 percent. A generalized flowsheet of washing and refining is shown in figure 1. General operating data are summarized as follows:

Water used in mining and treatment: 8 to 12 cubic meters per cubic meter of ore.

Installed power: 1 to 2 horsepower per ton of graphite produced monthly.

Labor performance: 20 to 50 kilograms graphite per man-day.

Some flotation concentrate for high-purity products is refined by further comminution in rolls or burrstones followed by screening, but this method is said to be inferior to controlled regrinding in ball mills followed by reflotation. Graphite with a purity exceeding 99 percent may be produced by chemical treatment of lower grade material with hydrofluoric acid or sodium hydroxide to remove silica. How-

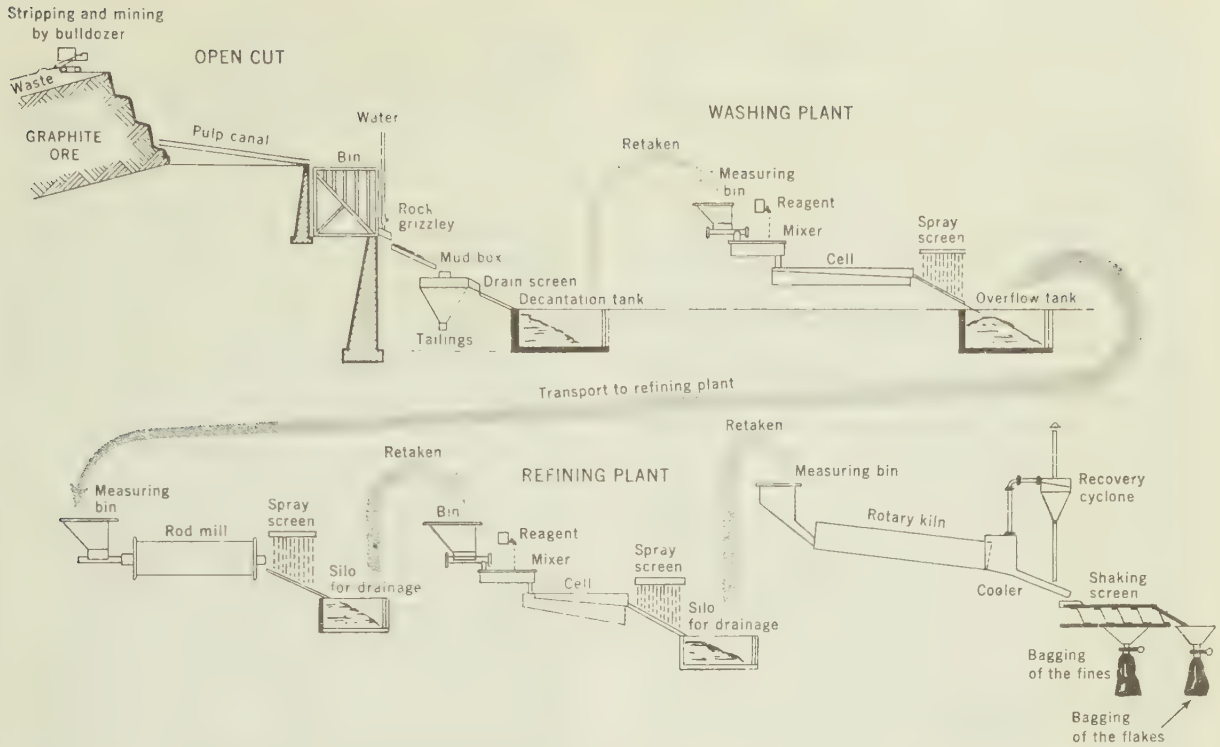

FIGURE 1.—Generalized flowsheet of Malagasy graphite mining and beneficiation.

ever, this treatment is expensive and is practiced commerically only in West Germany and France, and on an extremely small scale.

Manufactured Graphite (*6*)

The principal raw materials for manufacturing carbon and graphite products are petroleum coke, coal tar pitch binder, and a small quantity of petroleum-base oil to facilitate extrusion. The raw materials are simultaneously heated to about 150° C and thoroughly mixed, cooled to 100° C, extruded or molded to form the desired shapes, and baked at 950° C. The length of time the material is in the baking furnace varies with the quantity and size of the shapes, but usually is 11 to 13 weeks. After cooling, the carbon shapes are completed. Shapes to be converted to graphite are then transferred to graphitizing furnaces and heated to about 2,800° C to form soft, unctuous graphite. This operation, including heating, soaking, and cooling, requires 4 to 5 more weeks. The graphitizing takes place largely because of the temperature, but virtually all of the metal oxides (except part of the vanadium) in the raw carbon are reduced to metal and vaporized. Consequently, the graphitizing process is also a refining step.

During graphitizing, the electrodes and other shapes are packed in granulated or powdered metallurgical coke or graphitized material that has already gone through one or more furnace cycles. Part of this granular and powdered manufactured graphite is then sized and marketed.

Manufactured graphite varies considerably in physical and chemical properties, depending on the quality of the petroleum coke, grade and quantity of pitch, degree of preferred orientation imparted to the coke particles during extrusion, and maximum temperature and period of heating. The variables are too numerous and their interrelationship is not well enough understood to enable the routine manufacture of a product to close specifications.

Pyrolytic graphite is produced by thermal decomposition of a hydrocarbon gas in an evacuated chamber of absolute pressure of 4 to 6 mm of mercury by contact with a base (substrate) material of graphite that is maintained at an elevated temperature (plus 3,000° F). The carbon is deposited on the substrate as graphite crystals with the *a b* axial directions parallel to the surface of the substrate. Because of this crystal orientation, pyrolytic graphite is highly anisotropic. The mechanical strength, and electrical and thermal con-

ductivities parallel to the surface of the substrate is many times the value of these properties normal to the surface.

Graphite whiskers (single crystals) have been grown that have a tensile strength of 3 million pounds per square inch. This compares with a strength of 2 million pounds per square inch for iron whiskers.

Various grades of manufactured graphite are produced. Each manufacturer has a series of number and letter designations for his product. Special grades for nuclear applications are processed in the same manner as commercial grades, except that raw materials are more carefully selected and petroleum coke is used as a packing material during graphitizing instead of metallurgical coke (*10*).

Pyrolytic graphite is becoming available in limited quantities for experimental purposes. It is being used as structural and coating material where its relative hardness and anisotrophy are valuable. It is finding uses in the missile industry as rocket-motor nozzle liners and nose cones. It also may be used in the high-temperature reactor field as a low permeability coating for fuel elements.

Recrystallized bulk graphite also is in production. It has high strength at high temperatures and it has less creep at 3,000° C than conventional graphites have at 2,500° C. Recrystallized graphite shows superior performance in rocket-motor nozzles. It has good dimensional stability under neutron-radiation.

Fibrous forms of graphite—thread, yarn, felt, and cloth—now are available. They are finding application as thermal insulation, electric heaters, and as reinforcement for structural elements made of plastics or resins. Wooly and foam types of graphite also are available for use as high-temperature heat insulators.

USES

The major strategic use for Ceylon amorphous lump is for carbon brushes, for fractional horsepower motors and other electrical equipment, for high-altitude military aircraft and submarines, and for similar low-voltage applications. U.S. practice is to use lump containing 97 percent or more carbon, because it is known to perform satisfactorily under the severe operating conditions required. Substituting other grades would entail a prohibitive amount of bench testing of the end products to eliminate the risk of failure under operating conditions. The major strategic use for Malagasy flake graphite is in clay-graphite crucibles, which require coarse flake. Although the quantities needed are not large, these Ceylon amorphous lump and Malagasy flake graphites are important to domestic security and industrial activity.

The need for coarse flake graphite is decreasing, because crucible manufacturers are making silicon carbide-graphite crucibles in which the percentage of graphite is substantially less than in clay-graphite crucibles. One manufacturer has stated that silicon carbide-graphite crucibles require 18 to 25 percent graphite, compared with 45 to 50 percent for clay-graphite crucibles. Furthermore, much finer flake can be utilized. Domestic flake is said to perform satisfactorily and probably would be used if an assured supply could be obtained at a price comparable with that of Malagasy fine flake. Approximately 75 percent of the crucibles manufactured in the United States are silicon carbide-graphite crucibles. Complete substitution of silicon carbide-graphite crucibles for clay-graphite crucibles is unlikely; clay-graphite is used for special application, such as induction melting, and for large crucibles.

Manufactured-graphite shapes are used for electrodes, anodes, beams, blocks, brick, slabs, cylinders, metallurgical and chemical applications, bearings, bushings, nozzle and throat liners in jet engines, directional vanes in guided missiles, and moderators in atomic reactors. Manufactured-graphite powder is used in lubricants, brake lining, clutch facing, fabric belting, wire drawing, foundry facings, plastics, pigments, glass, dry-cell batteries, and other applications.

In Europe, large quantities of amorphous graphite are used in blast furnace charges to reduce the need for higher priced coke. The graphite is used as mined, without upgrading, for this purpose.

ALTERNATE MATERIALS

There is no satisfactory substitute for graphite in most applications. Some interchangeability is possible among all types and grades of natural graphite, and between natural and manufactured graphite, but the degree is difficult to determine. Because of its greater cost, manufactured graphite does not compete with natural graphite in most of its uses. On the other hand, natural graphite cannot be substituted for manufactured graphite in nuclear reactors because of the high neutron-absorption cross section of its usual impurities and because it is highly anisotropic and low in strength.

Manufactured graphite does not replace flake graphite in graphite-clay crucibles, although some crucibles are machined from manufactured graphite for special uses. The development of carbon-bonded silicon carbide-graphite crucibles (see "Uses") has reduced the quantity of

graphite needed for crucibles and the need for coarse flake. Other high-temperature refractory materials, such as the silicides, nitrides, and borides, may be suitable for uses now requiring graphite-clay crucibles.

RESERVES

Recoverable reserves of less than 5,000 tons of lump graphite occur in Montana with few veins having a strike length of as much as 50 feet. The veins range in thickness from less than 1 inch to about 2 feet; the quality of the graphite has not been determined.

No estimate of the amorphous graphite resource in Rhode Island is available, but it is very large.

Domestic deposits of crystalline flake graphite are low grade. Many of them contain less than 3 percent graphite, and most of them contain less than 5 percent; that is, they are about half the tenor of Malagasy ore. However, deposits in New York requiring underground mining, and others in Alabama, Pennsylvania, and Texas, which can be mined by open pit methods, contain a minimum of 600,000 tons of crystalline flake graphite. Only a small percentage is coarse flake that will meet specifications for crucible-grade graphite which must range from 8- to 60-mesh.

Quantitative data on reserves of amorphous and crystalline lump graphite in Ceylon are not available, but graphite veins cut igneous and metamorphic rocks in an area 95 miles long and about 40 miles wide in the southwestern part of the island. The veins range in thickness from less than an inch to several feet. Strike lengths range from a few to several hundred feet. Dips are nearly vertical, and some veins extend to a depth of at least 1,600 feet.

The reserve of amorphous graphite in Mexico is of the order of millions of tons. Large reserves also are known in Australia, Austria, the Republic of Korea, and the U.S.S.R.

The largest known reserve of flake graphite in the world is in the Malagasy Republic. Deposits occur in many individual districts throughout most of an area nearly 600 miles long and 100 miles wide. The graphite layers commonly are continuous for long distances; many can be traced for 3,000 to 4,000 feet along the strike. A few are up to 350 feet thick. Most of the commercial deposits are in the weathered outcrop of feldspathic gneisses, where tenor of the mined ore probably averages 5 to 6 percent graphite (*13*).

Large indicated reserves of crystalline flake reportedly occur in Australia, Austria, Brazil, Canada, China, West Germany, and Norway.

SOURCES OF STATISTICAL INFORMATION

Annual data on the production and shipments of natural graphite are obtained from domestic producers by the Bureau of Mines; annual data on consumption, by type of graphite and use, are obtained from consumers. No attempt is made to obtain detailed data from the many firms that consume less than 1,000 pounds per year. Some duplication results from reporting the same material as "processed for resale" by one establishment and "used" by another establishment. Frequently, consumers cannot identify the types and varieties of graphite in mixtures obtained from suppliers. However, the data collected are complete and accurate enough to be valuable in programing and mobilization planning. No data on stocks are published.

World production and trade data also are compiled by the Bureau from State Department dispatches and official publications of foreign countries, and U.S. exports and imports are obtained from the U.S. Department of Commerce.

PRODUCTION, CONSUMPTION, AND TRADE

World production of natural graphite, by countries, is given in table 1 for 1959–63, together with the 1954–58 average. It should be noted that the reported production for the Republic of Korea includes anthracite shipped to Japan and invoiced as amorphous graphite, presumably because of Japanese restrictions on imports of anthracite. Thus, it is doubtful that production of amorphous graphite from the Republic of Korea is much above its average output of 25,400 tons for 1949–53.

TABLE 1.—*World production of natural graphite, by countries*

[Short tons]

Country	1954–58 (average)	1959	1960	1961	1962	1963
Austria	20,718	68,444	97,043	89,255	98,416	109,778
Ceylon	9,109	8,816	10,107	10,016	9,665	9,280
Germany, West	11,892	12,377	12,760	13,349	13,134	13,000
Korea, North [1]	23,003	57,000	68,000	72,000	72,000	77,000
Korea, Republic of [2]	89,674	91,045	101,777	98,892	204,032	334,777
Malagasy Republic	15,719	12,614	15,923	16,473	19,274	17,319
Mexico	27,302	30,684	37,827	19,846	31,992	33,000
Norway	5,344	5,396	6,437	6,283	7,055	7,000
U.S.S.R. [1]	45,000	50,000	50,000	55,000	60,000	60,000
Other countries [1 3]	57,500	73,600	75,000	69,000	74,500	69,000
Total [1]	305,000	410,000	475,000	450,000	590,000	730,000

[1] Estimate.
[2] Includes an unknown but large tonnage of anthracite reported as graphite.
[3] Includes Argentina, Australia, Brazil, Canada, Czechoslovakia, Hong Kong, India, Japan, Kenya, Morocco, Republic of South Africa, South-West Africa, Spain, Taiwan, Tanzania, and the United States.

The average U.S. consumption for 1959–63 was 8 percent higher than for the previous 5-year period. A large increase in the use of amorphous graphite for refractories was chiefly responsible for the greater consumption.

Ceylon, the Malagasy Republic, and Mexico provided 89 percent of the U.S. imports of natural graphite during 1959–63, with Mexico supplying 72 percent (table 3). The remainder was received from 12 other countries and Hong Kong.

The rate of duty in effect in December 1964, for import of crystalline flake, valued at not over 5.5 cents per pound, was 15 percent ad valorem; for flake valued at over 5.5 cents per pound, 0.825 cent per pound; for lump and chip, 5.5 percent ad varolem; for amorphous graphite valued at over $50 per ton, 0.5 percent ad valorem. For amorphous graphite valued at $50 per ton and under, duty was suspended until June 30, 1966.

TABLE 2.—*Consumption of natural graphite in the United States, 1959–63 (average), by types and uses*

Use	Ceylon amorphous and crystalline lump		Other amorphous [1]		Crystalline flake		Total	
	Short tons	Percent	Short tons	Percent	Short tons	Percent	Short tons	Percent
Batteries			928	3	58	1	986	3
Bearings	74	2	56	(2)	44	(2)	174	(2)
Brake lining	246	7	466	2	413	6	1,125	3
Carbon brushes	322	9	330	1	131	2	783	2
Crucibles, retorts, stoppers, sleeves, and nozzles	14	(2)		(2)	3,302	44	3,316	8

1963	2,467	5,120	39,724	2,652	1,852	51,815	899

STRATEGIC CONSIDERATIONS

The United States has never been self-sufficient in any grade of graphite. Most amorphous and crystalline lump graphite are imported from Ceylon, virtually all crucible flake graphite from the Malagasy Republic, and all high-grade amorphous graphite from Mexico. Domestic production supplies only a small fraction of the peacetime needs. In case of an emergency, several low-grade deposits in the United States could be worked, but would require at least a year for development. The output from these domestic deposits, together with imported Mexican amorphous graphite, could achieve a measure of self-sufficiency for the United States. The cost, however, would be two to three times higher than the present market price of Malagasy flake. In addition, about 1,000 tons per year of Ceylon 97- to 98-percent carbon amorphous lump would be required for brushes in some motors and generators and other special uses.

GOVERNMENT PROGRAMS

Prior to World War II, the Government recognized that graphite from other sources could not be used efficiently for many purposes essential to military and civilian needs during wartime until new techniques of utilization could be established. As a result, certain grades of graphite deemed essential in wartime were designated as strategic and critical materials for stockpiling. Interim basic and maximum objectives were achieved for all strategic grades of graphite.

The stockpile program has been reevaluated in accordance with modern warfare needs. Many commodities were declared to be stocked in excess of requirements and a planned disposal was ordered. Certain grades of graphite were among those declared as excess stockpile materials, and an orderly disposal program was started in 1963.

Quantities of graphite in Government inventories are given in table 4.

The Office of Minerals Exploration, U.S. Department of the Interior, will participate in an exploration program for crucible flake graphite up to and including 50 percent of the approved cost.

TABLE 4.—*Graphite in Government inventories, June 30, 1964*

[Short tons]

	National (strategic stockpile)	DPA inventory	CCC stocks	Supplemental stockpile	Total
Ceylon amorphous lump	4,455			1,428	5,883
Malagasy crystalline	32,675			1,908	34,583
Other than Ceylon and Malagasy	4,809				4,809

PRICES

Oil, Paint and Drug Reporter, January 6, 1964, quoted prices for graphite as follows: Per pound, bags or fiber drums, exwarehouse, amorphous, powdered, 6 to 9.5 cents; crystalline, 88 to 90 percent, powdered, 19 to 21.5 cents; 90 to 92 percent, powdered, 21 to 24.5 cents; 95 to 97 percent, powdered, 29 to 31.5 cents; No. 1 flake, 90 to 95 percent, 29 to 31 cents; No. 2 flake, 90 to 95 percent, 29 to 31 cents. The prices quoted were unchanged from those published in 1958.

Prices quoted in E&MJ Metal and Mineral Markets, January 28, 1964, per metric ton, bags, f.o.b. source, except when otherwise noted, follow: Flake and crystalline graphite, Malagasy, $90 to $200; Norwegian, $80 to $140; German, $114 to $672; and Ceylon, per long ton, $95 to $250; amorphous, nonflake-cryptocrystalline, 80 to 85 percent carbon, Mexican, bulk, $17 to $20; Korean, bulk, $15; and Hong Kong, per long ton, $21. These prices show some changes from those quoted in 1958.

The quoted prices are only indicative of a range of prices between buyer and seller owing to the wide range of specifications. No prices are quoted for domestic production.

TAXES

Graphite producers are granted a depletion allowance for tax purposes of 23 percent on domestic production and 15 percent on foreign production.

RESEARCH

Research on natural graphite has not been extensive, but some efforts are continually directed toward improving methods of milling. A new flotation process for enriching amorphous graphite was recently developed and put to use in Austria (*3*). Research has developed new processes for using graphite in combination with various metals to form self-lubricating materials. Other new uses are occasionally developed, such as the use of amorphous graphite in European blast furnaces to replace part of the coke requirements.

Tests conducted by several manufacturers indicate that up to 10 percent domestic graphite could be mixed with Malagasy flake without greatly impairing the life of crucibles. Results from studies made by the National Bureau of Standards, U.S. Department of Commerce, indicate that domestic graphite of equivalent flake size and carbon content can be substituted entirely for Malagasy graphite without impairing crucible life (*5*, *6*, *8*). Past Bureau of Mines studies verify domestic flake of equivalent size and carbon content is equal to Malagasy flake.

Manufactured graphite has been the subject of substantial research both by industry and by Government agencies. Basic and applied research on oriented graphite is being conducted by an increasing number of firms with emphasis on missile and space vehicle applications. This stepped-up research on special graphite should lead to improved products, lower prices, and new uses. Several new types of special graphite lubricants have been developed, and research continues in this field. Another interesting area of research showing great promise for the future is the development of graphite fabrics.

Firms that have had a major role in the Government program to improve graphite, including pyrolytic graphite, are Union Carbide Corp., Carbon Products Division; General Electric Co., Hanford, Washington, and Schnectady, N.Y.; Lockheed Aircraft Corp., Palo Alto, Calif.; Raytheon Co., Waltham, Mass.; Bell Telephone Laboratories, New York, N.Y.; Atomics International (a division of North American Aviation), Canoga Park, Calif.; and Westinghouse Electric Co., Pittsburgh, Pa.

The U.S. Atomic Energy Commission continues its extensive research on manufactured graphite with respect to its uses in nuclear reactors.

In 1963, the American Society for Testing and Materials organized a committee, C–5, to promote knowledge, stimulate research, and develop test methods, specifications, and nomenclature for manufactured carbon and graphite products (*9*).

OUTLOOK

Both the short- and the long-term supply outlooks are favorable for graphite of all types required for the U.S. domestic economy. Output of all grades of Ceylon lump and Malagasy flake and fines is well below production capabilities, and producers in both countries are actively seeking additional markets. So long as supply lines remain open to Ceylon and the Malagasy Republic probably there will be no incentive for domestic consumers to attempt to develop alternate sources of supply, and the stockpile inventories will meet estimated essential wartime requirements even if no imports can be obtained.

The supply of domestic and Mexican graphite is ample, and productive capacity is greater than demand. Output undoubtedly will increase to meet the requirements of an expanding economy.

Graphite imports from sources other than Ceylon, the Malagasy Republic, and Mexico will be available on either a continuing or an intermittent basis; however, they are not essential, and other available types of graphite can be substituted for them.

There is no indication of a major increase in requirements for natural graphite. The shift to silicon carbide-graphite crucibles has reduced total requirements for crucible-flake graphite, and consumption of this type probably will not greatly exceed 4,000 tons a year. In a peacetime economy, the use of all other types of graphite in foundry facings, as a recarburizer in steelmaking, and for other applications will increase moderately.

New developments in manufacturing processes for graphite are important. The use of thermosetting plastics or furfuryl alcohol, to accelerate the graphitization of carbon, should increase. The method of producing oriented graphites by thermally decomposing hot carbonaceous gas on a hot substrate may lead to new or improved metallurgical applications in addition to space uses.

Special manufactured graphites that are denser, stronger, and more resistant to oxidation than conventional graphites are expected to find considerable use. Considerable interest has been generated in oriented and recrystallized graphites and present research may open new fields of use where their particular properties are required. However, the use of manufactured graphite in special applications, such as space vehicles and atomic reactors, is not likely to increase overall consumption greatly. Such uses receive spectacular publicity but they do not involve large quantities of materials.

PROBLEMS

A major problem of the natural-graphite-producing industry is the limited market for graphite of each type. Despite the fact that the free world prefers Ceylon and Malagasy graphite for most uses requiring high-quality graphite, producers in these countries must spend susbstantial effort attempting to widen their markets. This marketing problem is accentuated for other foreign and domestic producers.

Other sources of high-quality graphite usually cannot be exploited at a profit, because the demand is low and consumers are reluctant to change from satisfactory long-used sources to new sources that would require adjustments in formulas and manufacturing techniques, especially when there is no assurance of long-term continuing supplies from the new sources. Thus, even assuming that new producers could supply equal or superior grades of graphite at the same or lower prices than Ceylon and Malagasy Republic producers, their problem would remain one of marketing. Going concerns also face the difficulty of expanding markets for their products, because they are new to most potential customers.

Major technologic problems of the U.S. natural graphite industry are how to determine the degree of interchangeability possible among various types of graphite and among graphites of the same type from different sources, and how to reduce U.S. dependency on foreign sources of high-quality graphite, especially Malagasy crucible flake and Ceylon lump.

More reliable statistical information is required in order to properly evaluate the requirements, supply, and resources of the manufactured graphite industry.

A major fabrication problem of the manufactured graphite industry is to develop graphite with reproducibly constant properties for use as an engineering material. The variations in structure and properties within any single specimen or grade make present graphites unreliable for the severe service requirements in space applications.

Present emphasis has been on space-age applications of oriented and recrystallized graphites, but materials with such unusual strength and anisotropic properties must have other applications. Further research should develop less exotic but, perhaps more profitable uses.

The growth of whisker carbon and development of methods for testing all its properties alone and in combination with other materials is a problem worthy of more attention.

GYPSUM

By William R. Barton [1]

PLASTER made from calcining gypsum (derived from the Greek words for "earth" and to "cook") is one of the oldest building materials in the world and its use continues to grow. Since 1890 the annual production of crude gypsum in the United States has increased 56.8 times, reaching 10.4 million short tons in 1963; while demand for gypsum products multiplied 95.0 times to 14.7 million short tons in 1963. The value of the products sold or used in the United States in 1963 was $414.1 million.

In 1963, a total of 71 mines and 68 calcining plants comprised the domestic (primary) gypsum industry. There were three major firms with nine or more calcining plants plus mines and quarries; nine other calciners, seven of whom also operated mines; and a number of small firms producing only crude gypsum for uncalcined uses.

Large deposits of gypsum occur in various parts of the United States. However, cheap water transport makes imported gypsum more economical for many tidewater gypsum product plants. In 1963, imports, mostly from Canada, were about one-third of the apparent domestic supply. Gypsum and gypsum products exports are of minor importance.

Gypsum consumption is closely related to fluctuations in the building construction field. As the Nation's population and concomitantly its requirements for buildings grows, the need for gypsum will increase. Domestic consumption of gypsum products in 1975 will probably exceed 20 million tons.

BACKGROUND

The early use of gysum was principally in art. Chinese, Assyrians, and early Greek sculptors and architects worked to some extent in this medium. The first verified use as a construction material was as mortar in the pyramid of Cheops about 3000 B.C. Its real importance, however, has been its value as a fire-resistant construction material. Records of Roman laws indicate early familiarity with the fact that if fire attacks a gypsum plaster wall, formation of steam from chemically combined water will consume heat and retard combustion, and the remaining mineral portion of the wall is nonflammable.

Early master chemists, including Lavoisier and Le Chatelier, investigated the composition and properties of gypsum, but the material was put to little practical use until late in the 18th century when it was utilized as a fertilizer and soil improver in Germany and France. Benjamin Franklin, when acting as the American Commissioner to France in 1776, became interested in the use of gypsum land plaster and the use of plaster as a fireproof wall finish, and introduced the use of the mineral to the United States.

Its application for soil improvement gained rapid acceptance in the United States. Initially, gypsum imported as ballast from France and Nova Scotia was used. The mineral was discovered in central New York in 1792 and subsequently in Virginia (1835), Michigan (1840), Ohio (1850), Iowa (1872), Colorado (1875), and California (1875).

The early production from these deposits was limited to localized use as fertilizer. The calcining of gypsum for use as a plaster began in New York about 1835, but it was not until the middle eighties that a commercial method to retard the setting of gypsum plaster was developed. This revolutionary discovery marked the true beginning of the gypsum industry by permitting practical use of plaster in construction. Coupled with the simultaneous growth of the portland cement industry, that required crude gypsum to control the "set" of the cement, an ever increasing demand was created.

[1] Commodity specialist.

780-887 O—65——27

SIZE AND ORGANIZATION OF THE INDUSTRY

The U.S. gypsum industry has evolved to the point where most gypsum is mined and processed by large integrated manufacturers of building materials. A total of 71 mines and 68 calcining plants comprised the domestic industry in 1963.

The industry consisted of three major firms, each with nine or more calcining plants plus mines and quarries, nine other calciners, seven of whom also operate mines; and a number of small firms that produced gypsum or gypsite for cement retarder or agricultural purposes. The 10 large companies with mines accounted for 82 percent of U.S. crude gypsum output from 39 mines.

The United States Gypsum Co. is the principal producer of both crude and calcined gypsum. In 1963, this organization operated 13 mines or quarries in 13 States and 25 calcining plants in 17 States. National Gypsum Co. operated 7 mines or quarries in 7 States and 17 calcining plants in 16 States. Bestwall Gypsum Co. operated six mines or quarries in six States and nine calcining plants in nine States. United States Gypsum Co., National Gypsum Co., Kaiser Gypsum Co., and the Flintkote Co., operated large mines in Nova Scotia or Newfoundland, and United States Gypsum Co. operated mines in Mexico and Jamaica as well. In addition, new plants are planned for Georgia, Texas, Nevada, Arkansas, Montana, Florida, New Jersey, California, and Oklahoma.

The United States is the world's largest producer and consumer of gypsum, producing about one-fifth of the world's crude gypsum and consuming almost one-third of the world output.

The quantitative growth of the gypsum industry in the United States since 1890 can be visualized by realizing that by 1963 domestic crude production had increased 56.8 times and domestic consumption of gypsum and gypsum products had multiplied 95 times.

GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

In 1963 there were 71 active gypsum mines in 21 States. The leading producer was California with 17 percent of all raw gypsum mined, followed by Michigan, 13 percent; Iowa, 12 percent; and Texas, 11 percent. Fifty-five of the mines were open-pit and 16 were underground. Seventy-five percent of the Texas crude, 70 percent of the Iowa crude, and 28 percent of the Michigan crude were calcined within those States. Forty percent of the California production was sold uncalcined for agricultural use.

The calcining component of the domestic industry was represented by 68 plants in 29 States. The leading calcining States were New York (seven plants), California (six plants), Texas (six plants), and Iowa (five plants).

DEFINITION OF TERMS, GRADES, AND SPECIFICATIONS

The American Society for Testing and Materials has established specifications for gypsum and gypsum products.[2] They are too voluminous to quote in this report, but have been used in part to help promulgate the following definitions and are listed by number wherever applicable.

Gypsum, is the generic name for the mineral (hydrous calcium sulfate, $CaSO_4 \cdot 2H_2O$) variously known as selenite, a transparent cleavable form usually colorless; satin spar, a fibrous form with a silky luster; alabaster, a massive fine-grained variety, usually white and translucent; rock gypsum, a compact, granular form, coarser grained than alabaster; and gypsite, a soft, earthy impure form, noncoherent to slightly consolidated. In its pure state, gypsum is composed of 32.5 percent lime (CaO) 46.6 percent sulfur trioxide (SO_3), and 20.9 percent water. The importance of gypsum lies in its ability to lose three-fourths of its combined water upon application of moderate heat (between 250° and 400° F.) to form a hemihydrate. And its further ability, in hemihydrate form, to be molded upon addition of water, followed by a return to its rigid state upon "setting" (ASTM Specification C–22–50).

To obtain ultimate strength, lightweight aggregate carrying capacity, and other characteristics desirable in wallboard cores and plasters, companies prefer to use ore containing not less than 90 percent gypsum. Ordinarily, a gypsum deposit to be considered commercial and meet competition should have minable beds containing at least 80 percent gypsum. Color, density, and other factors also may be considered. Lower grade ores may be upgraded through use of heavy medium process to meet competition from other sources. In certain markets, such as soil conditioning, specifications often permit use of material containing as low as 50 percent calcium sulfate.

Anhydrite is an anhydrous calcium sulfate mineral ($CaSO_4$) usually massive and white or slightly colored. In its pure state, it is composed of 41.2 percent calcium oxide and 58.8 percent sulfur trioxide.

[2] Copies of specifications can be obtained from the American Society for Testing and Materials, 1916 Race Street, Philadelphia, Pa., for 50 cents each.

Land plaster, agricultural gypsum, is gypsum or gypsite used as a soil conditioner.

Calcined Gypsum ($CaSO_4 \cdot \frac{1}{2}H_2O$) is gypsum partially dehydrated by heating to between 250° and 400° F. This material is more popularly known as *Plaster of Paris* and is also called *Gypsum Hemihydrate* (ASTM Specification C–28–63 and C–59–50).

Dead-burned gypsum is gypsum completely dehydrated by calcining at 900° to 1,100° F. It is sometimes called *anhydrite* since its chemical composition is the same as the naturally occurring mineral.

Keene's Cement is dead-burned gypsum to which the property of quick setting has been restored by using certain salts. It has a hard finish and will take a polish. It is often used for ornamental plaster work (ASTM Specification C–61–50).

Accelerators are materials added to gypsum plaster to speed up natural set.

Retarders are materials added to gypsum plaster to slow up its natural set.

Gypsum board consists of a gypsum plaster core between paper outside layers.

Wallboard is used for walls and ceilings and is fastened directly on wood or metal framing or furring strips. The most popular thicknesses are, ⅜ inch, ½ inch, and ⅝ inch in standard 4 foot widths and various lengths (ASTM Specification C–36–62).

Gypsum Sheathing is water repellent, windtight board used for exterior sheathing without covering by building paper. It has a special water resistant paper incorporated as an outer layer and comes with tongue and groove edges. Its usual dimensions are ½ inch by 2 feet by 8 feet or ½ inch by 4 feet by 8 feet (ASTM Specification C–79–54).

Lath used as a plaster base is similar in construction to wallboard but is generally 16 inches by 4 feet and usually ¾ inch thick. It can be obtained with or without perforations or aluminum foil backing (ASTM Specification C–37–54). Several other forms including ceiling tile and laminated varieties are also sold.

Reinforced gypsum concrete is usually precast. It consists of calcined gypsum mixed generally with up to 12½ percent by weight of wood fiber, chips, or shavings and reinforced with steel bars or wire (ASTM Specification C–277–63).

TECHNOLOGY

Geology

Gypsum is abundant and widespread in the United States. Gypsum and anhydrite normally occur as sedimentary strata precipitated from saline waters, but occasionally they are found as a precipitate resulting from the chemical action of sulfuric acid and sulfates upon lime-bearing minerals, by the surficial disintegration and reaccumulation of pre-existing sediments as gypsum dunes, or as gangue minerals in ore deposits. The primary sequence of gypsum and anhydrite in sedimentary strata is determined by their order of precipitation as brine evaporates, the general sequence of major evaporite units being limestone, gypsum, anhydrite, salt, polyhalite with varying repetitions and omissions of strata being the rule rather than the exception. However, the present geological relationship of gypsum to anhydrite is largely secondary and is closely correlated with their depth below the surface. Gypsum preponderates in near-surface deposits, and anhydrite predominates at depths. This is generally attributed to the alteration of original anhydrite to gypsum by percolating ground waters close to the surface. The depth of alteration is affected by porosity and permeability of the strata and present and past water table positions. In New York, for example, alteration generally extends to a depth of 110 to 250 feet below the surface. In the United States gypsum beds rarely exceed 30 or 40 feet in thickness, but in the Canadian maritimes beds 40 to 100 feet thick are not uncommon. Common impurities are intercalated limestone and shale, clay, and sand. Because of their sedimentary mode of origin, deposits usually have wide lateral extent.

Mining

Most domestic gypsum is mined by open-pit methods. Underground mining is confined to deposits where the increased costs are compensated by higher quality ore, or proximity to the market.

The mining method selected to develop any particular deposit depends largely on the depth and composition of the overburden and the thickness and attitude of the gypsum deposit. The overburden may consist of glacial till, sand, gravel, alluvium, clay, limestone, shale, or other material. Overburden is removed by conventional earth moving equipment. In stripping, bank slopes are usually maintained at a $1\frac{1}{2}:1$ ratio. The number and width of berms or benches left during stripping are dependent on the depth of the ore from the surface. Stripping of the ore may become complicated if the surface of the deposit was exposed, prior to glaciation, to a weathering cycle which permitted portions of the deposit to be deeply dissected. The uneveness of this surface formed by action of the elements may present problems of contamination and in surface drilling. Maximum stripping ratio of waste to gypsum is

about 3:1, but in Canada 1:1 or even 1½:1 is the more common ratio.

In open-pit mines the blasting agents used are either ammonium nitrate-fuel oil or medium strength dynamite. In large open pits ore is loaded almost exclusively with power shovels, but in some thin bedded deposits it may be loaded with dragline excavators. The height of the benches generally ranges from 10 to 30 feet. Ore is transported from the pits by trucks, skips, trams, conveyor belts, or by combinations thereof. In mining, impurities (commonly shale, limestone, clay, or anhydrite) must be left, sorted out, or low-grade ore selectively removed to avoid contaminating the higher grade material preferred in the manufacture of calcined gypsum products. Often anydrite cannot be recognized easily, and careful sampling must be done to permit selective mining of gypsum.

Drainage problems are similar in most operations. Rain water and ground water are directed by ditches to strategically located sumps where the water is collected before being pumped from the pit and discharged into natural drainage features.

The room-and-pillar method is usually used when mining flat-lying gypsum deposits underground. Pillars range in size according to the condition of the roof and the thickness of the deposit. Under good conditions, 80 percent of the gypsum is recovered, but in sections of bad ground and weak roofs, larger pillars are left for adequate support. Where gypsum is not left as a roof or where the pillars can be drawn and the surface is allowed to cave, a deposit may be completely mined out. Roof bolts and timber may be used to strengthen slabbing roofs and areas weakened by solution cavities. Both percussion and auger drills are used in underground mines. The ore is broken by a medium-to-high velocity explosive detonated by conventional cap and fuse or by electricity. Broken ore is loaded and is transported underground by conventional methods. If beds are steeply dipping, drifting and shrinkage stoping are the mining technique normally used.

Beneficiation

Crushing operations at a gypsum mill consist essentially of two stages. The first may employ gyratory or jaw crushers, and the second hammer mills or roll crushers. Jaw or gyratory crushers reduce the crude ore as it comes from the pit to minus 3-inch size. The second stage crushers reduce the ore to minus ½-inch size, which provides a suitable feed for the rotary kiln or the grinding circuit.

Fine grinding is accomplished by tube and hammer mills, rolls, or other pulverizing equipment, either before or after calcination, depending upon the calcination process used.

The large quantity of high-grade gypsum available has discouraged any serious attempt to beneficate low-grade gypsum ore by flotation or gravity methods. Heavy medium separation equipment is used in a few localities for the beneficiation of gypsum ores. For efficient operation the feed must be thoroughly screened and washed to remove all fines. Beneficiation of gypsum may be effected by using a drum separator that employs a mixture of finely ground magnetite and ferrosilicon as the heavy medium. Heavy medium used in the process may be reclaimed from the sink and float products through the use of rinsing screens, drum electromagnetic separators, densifiers, and demagnetizing coils.

A method for flotation of silica from gypsum is used if silica free gypsum is required for glass or ceramic use (*1*).[3]

Processing of land plaster, gypsum cement retarder, fillers, or for other end uses requiring uncalcined gypsum, includes only crushing and grinding followed only by screening and classification.

Calcining

Calcining is the process of partly or completely dehydrating gypsum through the application of heat in gypsum kettles, rotary kilns, or under steam pressure in autoclaves. When kettles are used the gypsum must be ground before being calcined, but when a rotary kiln is used fine grinding is not required before calcination. Open pan and beehive, oven, or tunnel kilns are rarely used, particularly in the United States.

The properties generally desired in calcined gypsum include the following: High tensile and compressive strength, hardness, fineness of grind, and uniform setting time. Certain other properties are more essential for some applications of calcined gypsum than others. Plasticity is highly essential in hair-fibered wall plaster intended for use with aggregates. This property is not so important when calcined gypsum is used in manufacturing prefabricated products, such as wallboard and tile. The demand for plasticity also varies with the sand used in wall plasters, the lack of plasticity with a given amount and kind of sand can cause the mortar to work short. Mortar having an excess of plasticity is as objectionable as mortars that work short.

Kettle calcining is done with batches ranging from 10 to 20 tons per kettle. Ground gypsum is fed through charging doors into kettles

[3] Italicized numbers in parentheses refer to items in the list of references at the end of this chapter.

heated to 212° F. For 1 to 4 hours the charge is continuously stirred while temperature is gradually increased to 340° or 390° F, and then the material is discharged through a gate into cooling bins, each large enough to hold the contents of one kettle. Usually the kettles are emptied completely in 2 minutes as hot calcined gypsum flows freely. Between 30 minutes to 1 hour after the kettles are discharged, the material is removed from the cooling bins by conveyors and elevators and is transported to storage bins. In gypsum calcined in kettles, two distinct products are recognized, depending on the temperature reached during the process. The first and most important of the two products is "first settle" calcined gypsum drawn when the temperature reaches 325° to 340° F. It consists largely of the hemihydrate ($2CaSO_4 \cdot H_2O$) containing 5 to 6 percent water. The time required to calcine a kettle of raw gypsum to "first settle" material ranges from 1 to 3 hours, depending chiefly on the rate of firing, the fineness and purity of the raw material, and the kettle size and design. The second product is "second settle" calcined gypsum obtained by heating the kettle contents beyond the first settle stage to about 390° F. The "second settle" material consists chiefly of soluble anhydrite, which reverts to the hemihydrate on exposure to air. This material sets quickly, has higher tensile and compressive strengths, and is less plastic than the gypsum heated to 325° to 340° F. This material is also entirely different from the dead-burned gypsum formed by prolonged calcining at over 400° F.

Rotary kilns similar to those used by the portland-cement and lime industries are used for the calcining of crude gypsum. The kiln consists essentially of a slowly revolving cylinder inclined slightly from the horizontal, through which rock passes downward and is calcined to 325° to 340° F. by hot gases flowing counter to the flow of the rock. Kilns range in length from 70 to 155 feet and have diameters from 6 to 8 feet. Rock gypsum screened to ½-inch size is fed into the kiln at the high end. Passing through the kiln in about 45 minutes, the material is discharged directly into tube mills where the temperature attained by friction and impact is sufficient to calcine any unburned material. Overburning or underburning is prevented through the use of automatic controls which govern the temperature and rate of travel of material through the kiln. Advantages claimed for this kiln include high capacity, low labor costs, and relatively low fuel and power requirements.

Special plasters may be prepared in closed cylinders or autoclaves under steam pressure. No agitation is required, and as the temperature rises the water of crystallization is released and the hemihydrate is formed at about 250° F. The calcine produced by this method consists of particles that appear as short, broad base, dense crystals that possess properties different from other plasters. Less mixing water is needed to produce a smooth-flowing plaster with this material than required with ordinary plasters. When set, the plasters form a remarkably strong and dense product, useful wherever a product of superior quality is required.

Product Preparation

After calcination regrinding, mixing and blending prepares the gypsum plaster for use. If the plaster was produced in a kettle, grinding is not required, the product instead is simply passed over a vibrating screen. It is then mixed and blended with accelerators or retarders and any filler or binder required.

The setting time of calcined gypsum used in prefabricated products generally is accelerated. On the other hand, a retarder is used almost always in manufacturing wall plasters to control the time of setting to between 2 and 6 hours. Wall plaster is made by tube-milling calcined plaster of paris to very fine particle size. This material is thoroughly mixed with the retarder, fiber, and perhaps small quantities of other materials.

A great many substances have been used to retard or accelerate the set of calcined gypsum plasters. The action of these substances appears to be mechanical in that they hinder or help the crystallization of the calcined gypsum. Retarders are usually dispersing or deflocculating agents, whereas accelerators are coagulating or settling agents. Organic materials such as glue, gylcerin, flour, blood, and sugar are commonly used as retarders. In the United States the most commonly used retarder is a glue prepared by reducing hoof meal or low grades of hair with caustic soda. Potassium sulfate, alum, gypsum, or common salt may be used to accelerate the set of gypsum plasters.

Common admixed fillers and binders include asbestos, sand, sisal, sawdust and cork. If lightweight plaster or tile is to be the product, vermiculite or perlite are generally added. Sheet products are fabricated on a high-speed machine that automatically spreads a foamy plaster core between sheets of tough surface papers and cuts the resultant board to proper dimensions.

USES

The most important, and continually expanding, market for gypsum is the construction industry, especially in housing. Basecoat,

finish and acoustical plasters, wallboard, lath, sheathing, laminated, other board products, and ceiling tiles are the principal forms. The wide utility of these products is indicated in table 2. Prefabricated forms have been taking a continually increasing share of the construction market from wet plaster but due to market expansion total volume of both varieties has increased.

Gypsum has many uses in addition to those in construction. Three to 6 percent by weight of gypsum or anhydrite is added to cement clinker before it is ground. This quantity of gypsum or anhydrite in finished cement retards the setting and is an essential part of this important construction material. Ground gypsum is used on soils deficient in sulfate sulfur and as a soil conditioner. Applied to black alkali soils it transforms the sodium carbonate into calcium carbonate and sodium sulfate. It is also used in Europe for the fixation of volatile nitrogen in manure, converting the ammonium carbonate into ammonium sulfate.

An important market for calcined gypsum is for making models and patterns in industrial tooling activities. There are particularly heavy requirements in the aircraft and automotive industry. Calcined gypsum is used for the manufacture of molds. Requirements for this material include absorption of moisture from slip, sufficient strength, and that pitting of the mold must be retarded.

Pastel crayons or chalk utilize calcined gypsum in their composition. Small amounts of calcined gypsum are used in mixtures as an insulating filler between the walls of safes and filing cabinets and coverings for pipes and boilers. Calcined gypsum is used in surgery for orthopedic bandages and for plaster casts. When used in orthopedics, open-mesh bandages are impregnated with finely-ground calcined gypsum and rolled until ready for use. Calcined gypsum with especial retardation is employed in making casts of dental work. Ceiling and wall embellishments are made from calcined gypsum to which hemp fiber has been added. Calcined gypsum also is used in the casting of Babbit and other metals.

Calcined gypsum has many minor uses: Preparation of casts and protecting fossil remains during removal to museums; briquetting of coal; as a dehydrating agent; as a filler in paper and other products; as a setting for gold, silver, and stones for engraving and polishing; and in numerous articles such as facial powder, dental powder, etc.

Calcium sulfate is added in small quantities to water used by the brewing industry to promote enzyme action, assist in yeast fermentation, and to clarify the liquid.

Calcium sulfide is formed when an intimate mixture of ground gypsum and coke or charcoal is burned under reducing conditions. Calcium sulfide is used in the manufacture of medicine, luminous paint, and hydrogen sulfide; and as a base for calcium lithopone, insecticide, and fungicide.

Dead-burned gypsum finds use as a desicator and to dehydrate, or remove moisture, from gases.

Gypsum may be used as a substitute for sodium sulfate in a glass batch. It is claimed that the evolution of the combined water assists in clearing the glass melt. Gypsum plaster also is used by the glass industry for leveling up and holding the glass to the polishing table in the grinding and polishing of plate glass. This application faces a decline due to a technical change in plateglass production. The new "float glass" process involves the cooling of molten glass on a bed of molten metal, which produces a smooth surface without polishing and thus eliminating the need for gypsum in this application.

Fillers for use in wood, paints, textiles, and paper are made with gypsum or dead-burned gypsum. One of the principal uses of anhydrite is in the manufacture of ammonium sulfate. Used mainly in Europe, the process may be briefly described as follows: A solution of 25 percent ammonia is reacted with carbon dioxide forming ammonium carbonate, which in turn reacts with finely ground anhydrite, producing ammonium sulfate in solution and solid calcium carbonate. The ammonium sulfate is then recovered by filtration, crystallization, and drying.

The possibility of using gypsum or anhydrite as a raw material from which to manufacture sulfuric acid has attracted much attention because of the technical and commercial success achieved in Europe. Several chemical processes for accomplishing this have been tried; currently the most favored in England is that of calcining gypsum or anhydrite at high temperatures along with coke, silica, and clay, from which SO_2 and SO_3 gases (and a portland cement residue) result. These two gases then are converted to sulfuric acid.

Because of large alternative sources of sulfur, gypsum and anhydrite are considered to be uneconomical sources of sulfur in the United States; but if better methods are discovered or sulfur prices increase sufficiently, a new market for large-tonnage use of raw gypsum would be opened.

BYPRODUCTS AND COPRODUCT RELATIONSHIPS

Three tons of byproduct gypsum remain as residue for every ton of phosphoric acid made

during the production of superphosphate fertilizers from rock phosphate. In the United States, some of these residues are used for soil dressing, principally on tobacco fields. The waste material contains up to 10 percent residual acid and would require special treatment to make it suitable for other use. For most U.S. residues the cost of special treatment would exceed the cost of mining rock gypsum. A few piles of residue containing less acid than ordinary are reported to exist in this country. In Japan some residues of this type are reclaimed and used in the manufacture of plaster and wallboard, as cement retarder and for land plaster.

Byproduct gypsum also results in industrial processes when a calcium salt is neutralized by sulfuric acid and during the recovery of salt from sea water by evaporation. These gypsum residues are not used because of the exorbitant costs of purification except for gypsum recovered at a salt works in Taiwan for use in cement. As previously noted, when sulfuric acid is made from gypsum or anhydrite in Europe, byproduct portland cement or lime is marketed. This process is not used commercially to produce sulfuric acid in this country, but the Bureau of Mines has described one method of making sulfur dioxide and cement from gypsum in a fluidized-bed reactor (*7*).

ALTERNATE MATERIALS

Lime and hydraulic cement plasters compete to a limited extent with gypsum in the plaster field.

Wood, plastics, organic fibers, aluminum, and glass used for inside finishing compete directly with gypsum lath, wallboard, and sheathing.

Cement retarders such as calcium chloride, sugar, and certain other organic substances have occasionally been used but have not become serious competitors of gypsum.

Anhydrite is used to a relatively small extent for land plaster and cement retarder in the United States. It could also be used as a gypsum substitute in many other ways if gypsum suppliers in the United States were unable to meet demands (which is not likely in the forseeable future). In Europe anhydrite is used in making ammonium sulfate and, as mentioned before, is decomposed to make sulfuric acid and cement.

RESERVES

Gypsum deposits of good quality occur in many States. All of the States in the Rocky Mountain area have substantial deposits. Extensive deposits also are known in the western States of California, Kansas, Nevada, Oklahoma, and Texas. In the Midwest, Iowa, Indiana, Michigan, and Ohio are the principal sources; and in the East, New York and Virginia. No sizeable commercial deposits have been found in Wisconsin, Minnesota, northern California, the Pacific Northwest, the deep South east of Louisiana, or New England (*14*).

The measured resource of gypsum in the United States has been estimated to be sufficient to provide 2,000 years of output at present rates. Additional major reserves are available to U.S. consumers from Canada, Mexico, and the Caribbean Islands.

Anhydrite and phosphoric acid plant residues constitute additional latent resources if they are ever needed or become profitable to work.

So many regions throughout the world are endowed with gypsum desposits, that consumer nations are able to obtain the major part of their requirements from local sources. The world resources have been well described by the British Overseas Geological Survey's Division of Mineral Resources (*3*).

SOURCES OF STATISTICAL INFORMATION

Annual and quarterly data on the production, sales, and stocks of gypsum products are obtained from producers by the Bureau of Mines. World production data are compiled by the Bureau of Mines from foreign service dispatches and official publications of foreign countries, and figures on foreign trade are obtained from the Bureau of the Census. The Bureau of Mines publishes quarterly Mineral Industry Surveys on Gypsum and a comprehensive annual report is included as a chapter in Minerals Yearbook.

The Department of Commerce publishes Construction Review monthly which includes statistics on the utilization of gypsum products in the construction field.

PRODUCTION, CONSUMPTION, AND TRADE

Domestic crude gypsum production and consumption of gypsum products, during selected years, 1890 through 1963, is given in Table 1.

The United States in 1963 contributed about 19 percent of the total world production of 54 million tons of crude gypsum (a declining share at approximate constant volume). Table 2 shows the production and value of gypsum products sold or used in the United States in 1962 and 1963.

The value of all gypsum products sold in the United States in 1963 was $414.1 million and weighed approximately 14.7 million tons.

TABLE 1.—*Historical growth of the gypsum industry in the United States, for selective years, 1890 through 1963*

Year	Crude gypsum production (thousand short tons)	Gypsum products sold or used					
		Uncalcined except land plaster		Land plaster		Calcined	
		Thousand short tons	Value per ton	Thousand short tons	Value per ton	Thousand short tons	Value per ton
1890	183	19	$1.02	57	$2.53	79	$5.20
1919	2,420	470	2.83	40	4.64	1,596	8.90

[1] Includes uncalcined gypsum for use as filler and rock dust, in brewer's fixe, in color manufacture, and for unspecified uses.
[2] Includes dead-burned filler, granite polishing, and miscellaneous uses.
[3] Includes joint filler, patching, painter's, insulating, and unclassified building plasters.
[4] Excludes tile.
[5] Includes weight of paper, metal, or other materials.

Consumption, as measured by gypsum sold or used, is closely tied to general construction activity.

Most gypsum imports (table 3) are from Nova Scotia and are shipped by low-cost water transportation into the New England and Atlantic Coast States, while smaller but locally important tonnages are imported from San Marcos Island in the Gulf of Lower California (Mexico), Jamaica, and the Dominican Republic through ports on the Pacific coast and Gulf coast. Foreign ores, most of which are produced by subsidiaries of U.S. companies, account for approximately one-third of the apparent domestic supply.

[2] Less than $1,000.

Source: Bureau of the Census.

Exports are a very small portion of total sales, and a breakdown by country of destination is not made.

The United States does not levy a tariff on crude gypsum. Imports of ground or calcined gypsum are subject to a duty of $1.06 per short ton ($1.25 if from Communist nations). Gypsum board products are charged 12½ percent ad valorem.

STRATEGIC CONSIDERATIONS

Although the United States has adequate reserves of gypsum, the deposits are unevenly distributed throughout the Nation. Regional shortages exist, and consequently it is cheaper to import ore to serve major markets in the Atlantic, Gulf, and northern Pacific coastal areas.

The overseas sources could be disrupted by submarine activity in wartime and might require expansion of the domestic mining industry. However, during a war nonessential home construction would be restricted thus lowering the demand from gypsum products and concomitantly lowering ore requirements.

The calcining industry is sufficiently dispersed so that only a general nuclear holocaust could cause serious dislocations.

GOVERNMENT PROGRAMS

During World War II, the War Production Board sharply curtailed public and private construction, thus limiting the production of gypsum in most parts of the country. On the other hand, since the war the gypsum industry has benefited from government programs that have encouraged building construction.

The Area Redevelopment Administration program for depressed areas includes consideration of possibilities for gypsum mines and calcining plants as means of stimulating the economic growth of such localities.

PRICES AND COSTS

The average value of domestically produced crude gypsum has increased from $2.77 per short ton in 1949 to $3.67 in 1963. For imported ore the increase has been from $1.04 to $1.98 per short ton. The higher average values for the United States product are due to higher average mining costs (some of the U.S. mines are underground while foreign sources are almost entirely open-pit). U.S. mines are further handicapped by higher-cost rail shipment to plants compared with foreign mines shipping by water transport to U.S. seaboard calcining plants. Open-pit mining is preferred whenever possible to underground mining due to higher efficiencies per man and machine, lower development, and lower total operating costs. Some foreign open-pit mine costs are reputed to be only one-third those in some U.S. underground operations. A striking example of the effect of comparative mining and shipping costs, is that Nova Scotia open-pit mines can ship rock gypsum into the New York City area cheaper than underground mines in New York State. Values of imported versus domestic rock gypsum for selected years 1929 through 1963 are presented in table 4.

TABLE 4.—*Average values reported for crude gypsum mined in the United States and for imported crude gypsum, selected years 1929 through 1963*

[Per short ton]

Year	Domestic	Imported	Year	Domestic	Imported
1929	$1.97	$1.02	1959	$3.59	$1.93
1939	1.37	.90	1963	3.67	1.98
1949	2.77	1.04			

Values of gypsum products made from domestic, imported, and byproduct gypsum sold or used in the United States in 1962 and 1963 by users are shown in table 2.

TAXES

The U.S. income tax law grants domestic producers a depletion allowance of 15 percent of gross income from domestic and foreign crude production.

TRANSPORTATION

Transportation is a large factor in the economics of the gypsum industry. Gypsum ore and finished products are heavy, bulky, and relatively expensive to move; consequently product plants should be near the mine and the market area. A nearly ideal relationship of mine and plant to consuming areas exists in some areas, whereas in others, especially in the Western States and along the east coast, either the crude ore or the finished product or both must be shipped considerable distances. In some instances plants have been established in a consuming area and supplied with crude ore by water transportation.

RESEARCH

Leading firms of the gypsum industry maintain research laboratories and engineering staffs to improve methods of mining, crushing, calcining, and end-product manufacture.

Some long-range studies now in progress in industry relate to the chemistry of the material and seek to determine methods of application productive of maximum usefulness. These include studies of the general problem of adhesion of calcium sulfate plasters to other materials; studies of aggregates problems; studies of the effect of gypsum (retarder) content on comprehensive strengths of concretes; and studies of compressive strength of plasters mixed and applied under varying conditions by various methods.

Thermodynamic properties of gypsum and gypsum plaster were studied by the Bureau of Mines (*4*). Hydration rates were also studied (*2*).

The Gypsum Association and the Acoustical Materials Association study properties, specifications, and methods of using gypsum-bearing architectural materials.

OUTLOOK

The outlook for the gypsum industry is one of continued, long-term growth as the Nation's economy expands. Since World War II the industry has been characterized by expanding use of prefabricated gypsum products in preference to other building materials. This expansion, which is expected to continue, can be attributed to good insulating and fire-resistant properties, wide range of hardness and density, and an increasing need for less expensive rapid methods of construction. Other factors which are expected to sustain increasing gypsum output are—(1) the increase in the number of families; (2) Federal, State, and municipal programs of highway construction and slum clearance; (3) replacement of substandard housing; (4) the availability of funds for low-cost mortgages, and (5) the projected annual increase in gross national product.

Future demand for gypsum and gypsum products may be projected against consumption increases since World War II, projected future population growth (1.6 percent compounded annually), and projected increase in gross national product (3.8 percent compounded annually), and projected rise in the construction component of the GNP (4.8 percent compounded annually). Using these four methods, U.S. consumption of gypsum and gypsum products in 1975 would be 20 million, 17.7 million, 23 million, and 25.8 million, respectively. The last projection would probably be high owing to possible increased use of substitutes. However, consumption of more than 20 million tons in 1975 seems reasonable. Most of the increase will be supplied by processing imported ores at seaboard plants (many presently under construction or planned) with lesser increases in domestic ore production.

The continual development of new forms and variations of gypsum products for use in the building industry has fostered the growth of gypsum consumption in that field. However, continued competition will be experienced from alternative materials in the future, restraining the growth rate to some extent.

These competitor materials include wood, plastics, organic fibers, aluminum and glass, and they compete directly with gypsum plaster, lath, wallboard, and tile for inside finishing and with gypsum sheathing for exteriors. Gypsum, however, has an intrinsic advantage over some of these competitors in its fire resistant and retardent properties.

The growing factory-built concept for both housing and business room modules and complete homes has turned largely to nongypsum materials at present for finishing purposes, and if this industry increases its share of the construction market it may restrain demand increases for gypsum products.

The reserve situation will probably change comparatively little for many years. As reserves providing raw material to some plants become depleted, other sources may replace them if adequate prospecting programs are maintained. The United States will continue to rely on foreign sources for a portion of its crude gypsum needs; probably an increasing share owing to lower production costs and economical water transportation to U.S. seaboard processing plants.

There is only a slight prospect of gypsum or anhydrite being used as a raw material for producing sulfuric acid in the United States. The costs of using known processes are still too high to compete economically.

Some residue piles at phosphoric acid plants will find utilization at least for soil conditioner purposes.

PROBLEMS

There is a local problem of crude supply in areas far removed from deposits of commercial significance or in areas where the rate of depletion exceeds new resources being developed.

Lack of geographical and other commodity detail on gypsum products limits understanding of the structure and trends of the industry.

Expensive processing compared with alternate raw materials, blocks the use of gypsum as a raw material for the manufacture of sulfuric acid.

Competition from new construction materials, such as plastics for interior finishes, may intensify.

HAFNIUM

By Donald E. Eilertsen [1]

HAFNIUM, discovered in 1922 and available commercially for the first time during the last decade, has quickly assumed an important role in nuclear energy development.

The element always occurs with zirconium in minerals and is recovered commercially as a byproduct in processing zircon to zirconium. The United States and free world resources of hafnium in zircon are very large, but only a small fraction of the zircon consumption is destined to the production of zirconium and hafnium metals.

Four firms with facilities in Oregon, Ohio, West Virginia, New York, and Florida process zircon to hafnium primary products.

The separation of hafnium from zirconium is complicated and expensive. Most hafnium is utilized by the Atomic Energy Commission (AEC) as control rod material in nuclear reactors and in research and development in this field, but this market fluctuates sharply.

The United States is self-sufficient in hafnium and could be self-sufficient in zircon at premium prices.

Major problems confronting hafnium are the lack of commercial uses, high prices, and uncertain markets.

BACKGROUND

Hafnium always occurs with zirconium in minerals, and hafnium is so similar to zirconium chemically that hafnium was not positively identified until 1922.

The Bureau of Mines began developing the Kroll process for producing ductile zirconium-hafnium metal in 1945, and a pilot plant capable of producing 60 pounds of metal a week was started in early 1947. AEC and the Navy Bureau of Ships became interested in the metal, and production capacity increased to 5,000 pounds per month by October 1950 and nearly 25,000 pounds by September 1952 (*6*)[2]. Up to 1950 the hafnium was not removed from the zirconium, as the hafnium content does not detract from many uses of zirconium. However, for nuclear uses, hafnium in zirconium is detrimental, because the presence of hafnium increases the neutron absorption cross section of zirconium greatly and makes it less desirable as a structural material in reactors.

After 2 years' work sponsored by AEC at Oak Ridge, Tenn., a solvent extraction process was developed for the separation of zirconium and hafnium. The Bureau constructed a purification plant utilizing this process and began producing high-purity, low-hafnium (reactor-grade) zirconium in March 1951. Later the Bureau began producing high-purity hafnium sponge in a plant which attained a capacity of 7,000 pounds of hafnium and 300,000 pounds of zirconium by the end of 1953.

Late in 1953, Carborundum Metals, Inc., began producing hafnium-free zirconium and byproduct hafnium oxide, using essentially the process developed by the Bureau. As production at this plant increased, the Bureau plant was shut down July 1, 1955. In March 1956, however, requirements were reappraised and the Bureau plant was reopened, this time to be operated by Wah Chang Corp. under a 2-year contract from AEC to produce 300,000 pounds of reactor-grade zirconium per year. The hafnium oxide from both these operations was delivered to the Bureau of Mines for reduction to sponge metal.

The Bureau ceased hafnium production at the end of 1958. There were AEC contracts for hafnia production with various domestic firms, but these terminated in 1963. Following the loss of this market there was a decline in hafnium production.

SIZE, ORGANIZATION, AND GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

Four firms in the United States produce hafnium oxide in connection with zirconium output. They are the Carborundum Metals Co. Division, The Carborundum Co., Parkersburg, W. Va. and Akron, N.Y.; Columbia-National Division, Pittsburgh Plate Glass Co., Pace, Fla.; U.S. Industrial Chemicals Co., Division of National Distillers & Chemical Corp., Ashtabula, Ohio; and Wah Chang Corp., Albany Division, Albany, Oreg. In recent years all of these firms except Columbia National produced hafnium sponge.

[1] Commodity specialist.

[2] Italicized numbers in parentheses refer to items in the list of references at the end of this chapter.

Hafnium crystal bar producers in 1963 were Foote Mineral Co., Exton, Pa.; Wah Chang Corp., Albany, Oreg.; Nuclear Materials & Equipment Corp., Apollo, Pa.; and U.S. Industrial Chemicals Co., Ashtabula, Ohio.

DEFINITION OF TERMS, GRADES, AND SPECIFICATIONS

Hafnium (Hf) is a silver-colored metal. Some of its properties are as follows:

Atomic number	72
Atomic weight	178.6
Density—grams per cubic centimeter	13.09
Melting point ° C	2,220
Modulus of elasticity	20×10^{6}
Nuclear properties:	
Thermal neutron absorption cross section barns	115±15
Scattering cross section do	8±2

Hafnium metal as produced by the Kroll process is called hafnium sponge or "Kroll-process" sponge or metal. After refining by the iodide process, the metal is known as crystal bar hafnium, iodide metal, or ductile hafnium. High-purity hafnium derived from electrorefining is also ductile.

Zircon sand concentrate, including the hafnia content, is usually marketed on a basis of 66 percent zirconium oxide (ZrO_2) for domestic material and 65 percent ZrO_2 for imported material. Special high-hafnium zircon such as that from Nigeria usually commands premium prices.

Typical spectrographic analysis of the maximum impurities in hafnium crystal bar and grade 1 hafnium oxide produced by Wah Chang Corp. were reported as follows:

Impurities	Maximum impurities, parts per million	
	Hafnium crystal bar	Grade 1 hafnium oxide
Aluminum	30	<25
Boron	<.5	<.2
Calcium	<50	
Cadmium	<.5	
Cobalt	<10	<5
Chromium	30	<30
Copper	<10	<20
Iron	100	<200
Magnesium	1	<10
Manganese	<10	<10
Molybdenum		<10
Nitrogen	20	
Nickel	10	30
Oxygen	400	
Lead	50	<5
Silicon	30	50
Tin	<10	<5
Titanium	10	30
Vanadium	<20	<20
Tungsten	<50	
Zirconium	10,000–23,000	2,500

TECHNOLOGY

Geology

Hafnium and zirconium always occur together in minerals, but hafnium is always the minor constituent. The earth's crust has been estimated to contain 4.5 parts per million of hafnium compared with 220 parts per million of zirconium. Zirconium is a constituent of many minerals, but only zircon and baddeleyite are sold commercially. Zircon is the lone commercial source for both zirconium and hafnium metal.

Zircon, $ZrSiO_4$, is found as a minor constituent in acid igneous rocks, principally in granites, pegmatites, and granodiorites, in basic igneous rocks such as diabase and basalt, and also in sedimentary rocks such as limestone, sandstone, conglomerate, slate, schist, and gneiss. Zircon is rarely found in hard rock deposits in economically mineable concentrations. However, nature eroded many of these rocks, particularly the granitic rocks, and concentrated the heavy minerals such as ilmenite, rutile, magnetite, and zircon, in sand deposits along rivers, ocean beaches, and in dunes.

Zircon usually contains less than 2 percent hafnia, but there are exceptions. Nigerian zircon is known to contain almost 5 percent hafnia (*2*), and altered zircon may contain as much as 17 percent hafnia.

Baddeleyite, ZrO_2, occurs with zircon in weathered and eroded phonolite in Brazil.

Mining and Concentration

Zircon and baddeleyite are recovered from heavy-mineral beach sands or river gravels as coproducts and byproducts of ilmenite, rutile, monazite, and occasionally gold and cassiterite.

The components of heavy-mineral sands vary in different localities, but are principally magnetite, ilmenite, zircon, garnet, rutile, and monazite with small amounts of other dense and chemically and physically resistant minerals.

Mining of the heavy-mineral sands usually is by conventional dredging methods using bucketline, suction, or dragline dredges. The heavy-mineral rougher concentrator may be on the dredge, or on one or more barges attached to the dredge, or on land. The mineral constituents usually are separated from the rougher heavy-mineral concentrate in a mill on land. Spiral concentrators and electrostatic separators are extensively employed in the recovery and separation of zircon.

Metallurgy (*3*)

To separate hafnium from zirconium requires complicated metallurgical processing. Once separated, further processing of the pure hafnium oxide to metal follows the same methods employed in preparing zirconium.

Production of Crude Tetrachloride

Zircon sand, mixed with graphite or coke, is fused in an electric furnace to produce either the carbides or carbonitrides of zirconium and hafnium. The silica is volatilized as silicon monoxide, while the carbide melt builds up in the bottom of the furnace. When cool, the batch is removed and separated from any unreacted material. The carbide or carbonitride is chlorinated in a vertical-shaft furnace, and volatile chlorides are condensed in a nickel condenser, while silicon and titanium tetrachlorides pass out of the condenser.

Separation of Hafnium From Zirconium

The separation of hafnium from zirconium is costly but necessary to produce the hafnium-free zirconium required for nuclear reactors. Ordinarily zirconium, made without the hafnium separation and containing from 2 to 3 percent hafnium, is suitable for most nonnuclear uses. Separation processes that have been suggested include solvent extraction crystallization, ion exchange, distillation, selective partial reduction, vapor phase dechlorination, fraction precipitation, and caustic leaching, but many of these fall into a group of academic interest (*7*, *8*). Of these, the solvent extraction method has been adopted to the greatest extent. Although many different compounds were tested, among the best were systems using ammonium thiocyanate and methyl isobutyl ketone, or tributyl phosphate and nitric acid.

The crude or commercial grade mixed tetrachloride is dissolved in hydrochloric acid containing ammonium thiocyanate and fed to the top of a vertical glass column. The methyl isobutyl ketone (solvent) enters at the bottom of the column and being lighter than and immiscible with the aqueous solution, it rises upward through the aqueous solution and leaves at the top. As the solvent passes upward it extracts the hafnium thiocyanate preferentially and leaves the column with most of the hafnium and only a small part of the zirconium.

The remaining zirconium is removed by passing the solvent mixture through columns countercurrent to a hydrochloric acid solution, leaving only hafnium in the solvent. The hafnium is recovered from the solvent by passing sulfuric acid solution countercurrent to the solvent, and the resulting hafnium sulfate is converted to hafnium hydroxide by neutralizing with ammonium hydroxide. The hafnium hydroxide is dried and calcined to the oxide. The hafnia content in the hafnium product averages 98.8 percent, the chief impurity being zirconia.

Hafnium Metal Production (*3*, *6*, *8*)

Hafnium oxide is mixed with carbon, sucrose, and a small amount of water, then briquetted, dried, and chlorinated in a vertical-shaft chlorinator.

The hafnium chloride is purified by injecting the vapors into a molten mixture of potassium chloride (KCl) and sodium chloride (NaCl), containing a small quantity of metallic sodium. Impurities, such as aluminum and iron, form complexes with the salt bath and remain in the bath. High-purity hafnium chloride volatilizes from the salt bath and is reacted with a mixture of sodium and magnesium in a reaction crucible. The reaction is exothermic and the temperature is carefully controlled by the rate of addition and by dilution of the gaseous hafnium tetrachloride ($HfCl_4$) with an inert gas. The sodium reacts first, and all of it is reacted before the reaction-zone temperatures attain 800° C. The reduction is completed by the excess of magnesium present.

When the reaction is completed and the furnace has cooled, the crucible with its charge is removed and placed in a distillation furnace where it is heated to about 960° C in a vacuum. The magnesium chloride-sodium chloride binary salt and excess magnesium are melted, volatized, and collected in a condenser attached to the furnace. After cooling, the residual hafnium sponge is removed from the crucible, cleaned in a helium-atmosphere box, and then chopped carefully with a single blade cutter to minus $\frac{3}{8}$-inch.

Refining Hafnium Sponge

Sponge zirconium and titanium, similarly produced, would be ready for melting and fabricating. Hafnium, however, requires additional purification for some uses. Like zirconium and titanium it is hardened and embrittled by oxygen and nitrogen. Kroll-process sponge hafnium contains from 1,000 to 1,500 parts per million oxygen (0.10 to 0.15 percent), and it is necessary to bring this below 500 parts per million to obtain hafnium ductile enough to be rolled, drawn, or extruded readily.

Refining may be accomplished by the iodide process developed by J. H. de Boer (*5*), by electrorefining, or by electron beam (*7*). In the de Boer method hafnium sponge reacts

readily with iodine vapor at about 600° C to form hafnium tetraiodide, which volatilizes. The iodide reversibly dissociates into hafnium and iodine at about 1,600° C. A fine tungsten wire heated electrically provides the heat and energy for decomposition. In a closed system with an inert atmosphere, the iodine can return for more hafnium, with the result that the sponge metal is transferred to the filament where it builds up to a rod from ½ to 1 inch in diameter. Fortunately, hafnium oxide, nitride, and some other impurities transfer at a much slower rate, so the net result is to obtain a very pure and ductile hafnium.

Methods employed by the Metals Co. Division of the Carborundum Co., Akron, N.Y., to process Nigerian high-hafnium zircon to hafnium ingot were published (*1*). The procedures used to process zircon to hafnium ingot are essentially the same as previously described except that hafnium sponge is refined and purified by electrorefining methods, the resultant product being high-purity hafnium flake used to make ductile hafnium shapes.

Melting and Fabrication

Hafnium from the iodide or electrolytic method is melted and fabricated in much the same fashion as zirconium and titanium (*1*, *3*, *6*, *8*). A consumable electrode of the compacted metal is arced against a pool of molten metal in a water-jacketed copper crucible, and the resulting ingot can be fabricated by methods similar to those used for zirconium and titanium.

USES

Zirconium and hafnium metal production have accounted for only a small fraction of the U.S. consumption of zircon as output of this mineral has been used mostly for foundry sands, refractories, ceramics, abrasives, and chemicals.

Hafnium's largest use by far is in nuclear reactors as a control rod material to absorb thermal and epithermal neutrons. It is highly resistant to radiation damage as well as to ordinary chemical corrosion.

A number of applications have been developed for hafnium but very few are in use. Uses developed and suggested are as filaments in electric light bulbs, as electrodes in X-ray tubes, rectifiers, and high-pressure tubes, as a "getter" in vacuum tubes to scavenge traces of oxygen and nitrogen, in photographic flash powders, as a component of detonating caps and ammunition, and in bright coatings for ceramic decoration. A number of hafnium alloy systems have been developed (*4*, *7*).

BYPRODUCTS AND COPRODUCT RELATIONSHIPS

Zircon, the commercial source of zirconium and hafnium, usually is recovered as a coproduct but sometimes as a byproduct while dredging heavy-mineral sands for titanium minerals. Zircon output is thus largely dependent upon the demand for titanium minerals.

Hafnium is recovered as a byproduct in processing zircon to zirconium. It is too costly at present to produce hafnium by itself from zircon.

ALTERNATE MATERIALS

Hafnium has preference in nuclear reactors where high cross section and high-temperature corrosion resistance are desirable. It has advantages over substitute materials because it is resistant to water corrosion, is stable under the intense radiation within a reactor, and does not require cladding or other difficult fabrication operations. However, boron, cadmium, samarium, europium, gadolinium, and even gold, silver, and platinum also have high cross sections and have been used for reactor control. Of these, cadmium and boron appear to be most competitive with hafnium. For instance, either hafnium, boron steel, or stainless-steel-clad silver-cadmium-indium alloy control rods have been mentioned as being suitable for pressurized water reactors.

RESERVES

Hafnium is extracted commercially as an impurity from zircon. The zircon resources of the United States and free world were compiled in the 1961 Minerals Yearbook. These figures can be used to estimate roughly the potential hafnium resources by assuming that zircon contains an average of 1 percent hafnium.

The hafnium resources of the United States and free world are shown in tables 1 and 2.

TABLE 1.—*Estimated hafnium resource in zircon of the United States*

State	Zircon, thousand short tons	Hafnium, short tons
California	1,500	15,000
Florida	7,155	71,550
Georgia	345	3,450
Idaho	82	820
Maryland	162	1,620
New Jersey	1,520	15,200
New Mexico, Utah, Wyoming	290	2,900
Oregon	90	900
South Carolina	1,350	13,500
Other States	87	870
Total	12,581	125,810

TABLE 2.—*Estimated hafnium resource in zircon of the free world*

Country	Zircon, thousand short tons	Hafnium, short tons
Australia	2,882	28,820
Brazil	2,552	25,520
Ceylon	1,000	10,000
India	3,360	33,600
South Africa, Republic of	564	5,640
United States	12,581	125,810
Other countries [1]	404	4,040
Total	23,343	233,430

[1] Includes Republic of Ivory Coast, Republic of Korea, Malagasy Republic, Nigeria, and Uruguay.

STATISTICAL INFORMATION, PRODUCTION, AND TRADE

The Bureau of Mines canvasses domestic producers for statistical data on zirconium mineral concentrate, zirconium metal and its alloys and compounds, and hafnium metal and its compounds.

Data on domestic zircon production are withheld to avoid disclosing individual company confidential data. In 1963 the domestic production of hafnia was reported at 65 tons.

The Bureau of the Census collects import and export data on zirconium minerals, and import data on unwrought, waste, scrap, and wrought hafnium. Export data on zirconium and hafnium are not available. Zirconium ore and concentrate are imported duty free. Unwrought hafnium is dutiable at 10.5 percent ad valorem.

STRATEGIC CONSIDERATIONS

The United States is self-sufficient in zirconium and hafnium metals and could be self-sufficient in domestic zircon if required but at increased prices. The AEC has an inventory of hafnium for its use.

GOVERNMENT PROGRAMS

Zirconium mineral concentrate is not being bought by the Government for the national strategic and supplemental stockpiles. Stocks of zircon (1,920 tons) and baddeleyite (16,533 tons) in the strategic stockpile on Dec. 31, 1964, are destined for disposal. Hafnium is not acquired for the national strategic stockpile.

PRICES

Domestic zircon, containing 66 percent ZrO_2, fob Starke, Fla., is quoted at $47 per short ton. Imported zircon containing 65 percent ZrO_2, cif Atlantic ports is quoted at $61 per long ton.

Quoted prices for hafnium sponge and hafnium bar and plate are $75 and $138 per pound, respectively.

TAXES

The domestic depletion allowance is 23 percent, whereas the foreign depletion allowance is 15 percent.

RESEARCH

Hafnium has undergone substantial research and development since 1951 when keen interest focused on its use as control rod material in nuclear reactors.

The production of hafnium was achieved only after a very intensive research program subsidized by the Government through AEC and the Department of Defense. Most of the research was closely associated with the development of zirconium. The Bureau of Mines participated in this program, particularly in developing laboratory processes into workable commercial operations, in developing melting, casting, welding, and other fabrication techniques, and in developing alloys.

Research and development on hafnium at present is mainly on hafnium and zirconium separation and purification, developing alloy systems, and preparation and fabrication of hafnium carbide.

OUTLOOK

The demand for hafnium and its alloys and compounds is expected to increase moderately in the foreseeable future.

Hafnium output will continue to be derived as a byproduct in the recovery of zirconium from zircon even though it might be necessary at times to use high hafnium-bearing zircon as source material for larger yield of hafnium.

The demand for hafnium in nuclear reactors will depend on the demand for new reactors and how well hafnium can maintain its preference over other metals.

Larger consumption of hafnium in established markets and new commercial uses for hafnium through research and development will be vigorously sought.

Hafnium prices will probably fluctuate according to the demand for the metal.

780-887 O—65——28

PROBLEMS

The major problem confronting hafnium is the lack of commercial uses, caused mostly by high prices, uncertain markets, and undeveloped technology.

The largest demand by far for hafnium has been in nuclear energy and in research and development in this field. This demand has varied greatly. Actually, only a few small commercial applications have been developed for the metal. Consequently markets are needed not only to alleviate the fluctuating demand in nuclear energy but also to make greater use of this comparatively new metal.

Currently, hafnium output is controlled by the demand for zirconium as a large portion of the cost of extracting hafnium is borne by zirconium. High hafnium-bearing zircon such as that from Nigeria can be used to increase the yield of hafnium but extraction costs are high and the resources small.

Problems associated with the development of economical hafnium lie in all stages from discovery of new sources through recovery, refinement, disclosure of new physical and chemical properties, and fabrication of the metal and its alloys and compounds.

HELIUM

By Harold W. Lipper [1]

HELIUM, an element with a rare combination of unique properties and a wide range of vital uses, occurs as a minor constituent of some natural gases. Waste of this limited and irreplaceable resource is curtailed by a long-range helium conservation program carried on by the Bureau of Mines. Large quantities of helium, formerly lost in the burning of helium-bearing natural gas, are recovered and stored for use in the future. Without such a program it is doubtful that enough helium could be recovered from helium-bearing natural gas remaining after 1985 to meet predicted future helium demand (*32*).[2] With the program there is good assurance that adequate supplies of helium will be available beyond the year 2000.

The Bureau owns and operates five helium production plants that supply high-purity helium to meet current demands of the Federal agencies and some commercial customers. Helium to meet future demands is purchased by the Bureau under 22-year contracts in a $47.5 million-a-year helium conservation program from five plants financed, built, and operated by private industry. These plants recover helium that would otherwise be wasted when helium-bearing natural gas is used for fuel and deliver it to a 425-mile pipeline system owned and operated by the Bureau. The purchased helium is stored underground in a partially depleted helium-bearing natural gas formation for later withdrawal and sale. During the life of the present contracts for helium conservation, the five industry plants are expected to deliver 62.5 billion cubic feet of helium. Production from Bureau plants of 15 billion cubic feet would bring the total volume of available helium to 77.5 billion cubic feet. Helium sales are predicted to be 36 billion cubic feet, leaving 41.5 billion cubic feet in underground storage for later use. When the present contracts expire, about 35 billion cubic feet of helium will remain in unproduced, known helium-bearing natural gas sources. The stored helium is likely to be the primary source of supply after about 1985.

Helium has become progressively more important in a wide variety of uses since 1918 when the Bureau and three private firms under U.S. Navy sponsorship pioneered the process for extracting helium from natural gas. Through World War II helium was used almost exclusively as a lifting gas in lighter-than-air ships, and total requirements were met from a few small plants operated by the Bureau. Burgeoning requirements for helium accompanied the technological explosion that followed World War II and taxed severely the capacity of existing plants to supply needs that have grown at 20 percent a year since 1950. Helium use in 1950 was 81 million cubic feet. By 1958 demand rose to 352 million cubic feet, and a plant supplying 300 million cubic feet a year was built by the Bureau at Keyes, Okla., in 1959. Total helium demand for 1964 is expected to be about 700 million cubic feet. Federal agencies will take about 75 percent of the total volume, and the remainder will be delivered to commercial users or distributors who purchase helium from the Bureau for resale. About 6 percent of the total requirement will be met by production from a private plant in Arizona which operates independently of the Government helium program.

More than half the helium used each year is for pressurizing liquid fuels in missiles and space boosters such as Atlas and Saturn. This use and helium-shielded arc welding, leak detection, gas chromatography, helium-cooled nuclear reactors, low-temperature work near absolute zero, synthetic breathing mixtures for undersea exploration, and new uses are expected to require 2 billion cubic feet of helium a year by about 1990.

Fundamental research on helium is carried on by Government agencies, universities, and nonprofit organizations.

BACKGROUND

Discovered on the sun in 1868, helium was only known to occur there until 1895, when it was found on earth in a gas extracted from the uranium-bearing mineral cleveite. The occurrence of helium in natural gas, which is the sole source that is of economic interest today, was discovered in 1905. The first effort to use this unique resource was in 1917 when the need for a safe nonflammable gas for airships generated interest in helium. Under sponsorship of the Navy Department, which provided funds and development contracts with private industry, the Bureau began its work with helium in 1918; since 1921 helium has been produced and sold in quantity by the Bureau. Interest in helium for lighter-than-air craft extended after World War I, and the Bureau of Mines built a small helium plant at Fort Worth, Tex., that operated until 1929. A new technology resulted from this pioneering effort, and an economically feasible way was developed for extracting helium from helium-bearing natural gas by a low-temperature gas liquefaction process.

After the loss of the great rigid airships during the 1930's helium consumption declined greatly. However, the Bureau continued helium operations, supplying helium to the Navy for use in nonrigid aircraft, designated blimps, and to the Weather Bureau for use in weather balloons. Minor amounts were sold to research laboratories, hospitals, and industry. During World War II, the Bureau built four new helium extraction plants and enlarged the Amarillo, Tex., plant to provide helium for the many blimps used by the Navy on antisubmarine and other patrols. This military demand for helium soon declined but war-time technology had developed requirements for helium of higher purity than the 98.2-percent product that was adequate for use in lighter-than-air craft. To provide higher purity helium for welding aluminum and other metals, an improved low-temperature helium purification process was designed, developed, and placed in operation during the late 1940's. The new process produced helium having a purity of 99.995 percent and is the basic purification process in use today.

A boom in helium demand began in 1950, almost simultaneously with the availability of high-purity helium. Since then the annual demand for helium has increased about 20 percent a year. Although inactive Bureau plants were returned to production, by 1955 demand exceeded the capacity of the four existing plants. The Exell plant at Masterson, Tex., was enlarged in 1956 to triple its capacity, but the increased production was needed immediately in the Nation's space program. Periodically during the 1950's, helium was in short supply owing to the limited capacity of Bureau plants. Construction of a new plant at Keyes, Okla., in 1959 having a capacity of 300 million cubic feet per year, ended the shortage.

The new plant assured an adequate helium supply for the present, but continuing studies showed that the Nation's future supply of helium depended largely on a long-range conservation program to recover helium that was wasted to the air when helium-bearing natural gas was used for fuel.

Enabling legislation for a long-range helium conservation program Public Law 86–777, amending the Helium Act of 1925 as amended (43 Stat. 1110; 50 U.S.C. 161, 163–166) became effective March 1, 1961. It made helium conservation possible by authorizing long-term (up to 25 years) contracts for the purchase of helium. All of the available contracting authority has been used in 22-year contracts with four companies. The companies financed, designed, and built five plants to extract helium from helium-bearing natural gases that supply fuel markets. The plants deliver helium to the Bureau's pipeline system where it is transported to the Cliffside gasfield near Amarillo, Tex. Helium acquired for conservation is stored underground in the gasfield for later withdrawal and purification to augment the supply available from remaining helium-bearing gas supplies. Additional information concerning the helium conservation contracts is shown in table 1.

SIZE, ORGANIZATION, AND GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

Until late 1961 the only helium extraction plants in the free world were the five plants owned and operated by the Bureau of Mines. Completion of the Kerr-McGee Oil Industries, Inc., plant at Navajo, Ariz., in December 1961 marked the first private industry production, independent of the Government's helium program, since the 1930's when small private plants were operated for a time at Dexter, Kans., and Thatcher, Colo. The Bureau plants, the Kerr-McGee plant, and a small plant in Canada produce and market high purity helium. The five plants built by industry in the long-range helium conservation program produce a product called crude helium, which is a mixture of helium and nitrogen.

TABLE 1.—*Contracts for helium conservation*[1]

Company (parent companies in parentheses)	Plant location	Initial unit price (1,000 cubic feet)	Maximum annual obligation (millions)	Estimated helium volume (million cubic feet)	
				Annual average	Life of contract
Northern Helex Co. (Northern Natural Gas Co.).	Bushton, Kans	$11.24	$9.5	675	13,500
Cities Service Helex, Inc. (Cities Service Co.).	Ulysses, Kans	11.78	9.1	610	12,200
National Helium Corp. (Panhandle Eastern Pipe Line Co. and National Distillers & Chemical Corp.).	Liberal, Kans	11.78	15.2	1,053	21,060
Phillips Petroleum Co	Dumas, Tex., and Hansford County, Tex. (2 plants).	10.30	13.7	788	15,766
Weighted average		11.29			
Total			47.5	3,126	62,526

[1] All contracts were let during 1961.

At the Bureau's Exell, Tex., Keyes, Okla., and Otis, Kans., plants, supplies of helium-bearing natural gas for processing are obtained through contracts with private companies that own and control the respective gas supplies. Helium-bearing natural gas from company pipelines is diverted to the plants. After the helium is extracted, the remaining natural gas is returned for transmission to fuel markets. Shrinkage of the helium-bearing natural gas stream through Bureau plants averages about 8 percent of the inlet volume. Such shrinkage comprises the helium and a small amount of nitrogen that is removed with the helium plus the natural gas used as fuel at the plants.

Helium-bearing gas for the Amarillo, Tex., plant comes from the nearby Cliffside gasfield in which the Government has owned gas rights since 1929. After removal of helium, the remaining natural gas is sold by the Government under a life-of-the-field contract to a gas-producing company for disposal as fuel. At the Bureau's Navajo helium plant near Shiprock, N. Mex., helium-bearing natural gas is obtained under gas purchase contracts from nearby privately developed wells. The gas is nonmerchantable as fuel because of its low heating value.

At Navajo, Ariz., the Kerr-McGee plant extracts helium from a company controlled source, the Pinta Dome field. Here the gas is essentially a mixture of helium and nitrogen (*27*). A similar situation exists in connection with the Canadian Helium Limited plant in Saskatchewan, Canada, near Swift Current (*25*). Table 2 gives capacity and other data for all known helium extraction plants in the free world.

DEFINITION OF TERMS, GRADES, SPECIFICATIONS, AND PROPERTIES

All helium produced at Bureau plants is 99.995 percent pure and is designated grade A. Other gases (mainly neon, nitrogen, and hydrogen) total not more than 50 parts per million by volume (*16*). The Bureau sells helium in no other grade. Grade A helium is measured as a gas in cubic feet at a base pressure of 14.7 pounds per square inch absolute at 70° F. The Kerr-McGee plant furnishes helium that is comparable to the Bureau's Grade A helium.

Helium purchased by the Bureau for conservation is a mixture of helium and nitrogen, but small amounts of hydrogen and hydrocarbons may be present. The mixture is measured at a base pressure of 14.65 pounds per square inch absolute at 60° F. Payment is for the helium contained in the mixture delivered to the Bureau's pipeline.

Helium is a monatomic, chemically inert gas. Next to hydrogen it is the lightest of all gases. At 14.7 pounds per square inch absolute and at 70° F, 1,000 cubic feet of helium weighs 10.34 pounds. A like volume of air would weigh more than 76 pounds. Helium liquefies at −452.13° F, just 7.69° F above absolute zero. Liquid helium is generally sold by the liter. A liter of liquid helium is equivalent to 26.63 cubic feet of gas. Helium remains liquid down to essentially absolute zero and is the only gas known to behave in this manner. It solidifies or freezes only under pressure. Publications listed in the references section (*2–3, 10, 26*) present additional information on the properties and characteristics of helium.

TABLE 2.—*Data on helium plants*

Plant	Ownership	Initial operation	Approximate average helium content of gas stream (mole-percent)	Approximate annual capacity (million cubic feet)	Helium content of product (mole-percent)
High-purity helium plants:					
Amarillo, Tex.	Bureau of Mines	April 1929	1.8	60	99.995
Exell, Tex.	do	March 1943	.9	280	99.995
Otis, Kans.	do	October 1943	1.4	50	99.995

TECHNOLOGY

A survey to determine the Nation's helium resources has been carried on in all natural gas producing areas of the United States since inception of the Government's helium program in 1917. Sampling and analysis techniques have been described in detail (*1, 4, 22–24*).

Some large natural gasfields contain no helium, or helium is present only in trace amounts (less than 0.05 percent). Gas from the Hugoton and Texas Panhandle gasfields normally contains 0.3 to 1.0 percent helium. Some relatively small, isolated fields, such as the Table Mesa and Hogback fields of New Mexico, contain gas having about 5.5 percent helium. Gas from the Pinta Dome field contains 8.2 percent helium.

Helium is extracted from helium-bearing natural gas by a low-temperature gas liquefaction process (*12*). At Bureau plants the helium-bearing natural gas stream is cooled to a temperature that is below the liquefaction point of the hydrocarbon components but is above the liquefaction point of helium. A separation is then made of the gas, which is mostly helium, and the liquid, which is mostly hydrocarbons. The product of this separation is called crude helium, which is a mixture of about 70 percent helium and 30 percent nitrogen. The crude helium is compressed, cooled until most of the nitrogen is removed, and passed through activated charcoal at the temperature of liquid nitrogen (−320° F), for final purification. The resulting 99.995-percent pure helium is then put into shipping containers.

Although the basic low-temperature helium extraction process in use today was developed by the Bureau of Mines, the technology for helium extraction took great strides forward when the five new helium conservation plants were built. Daily helium-bearing natural gas processing capacity of the plants for helium conservation is 7 to 11 times greater than that of the largest Bureau plant. This feature required the design and construction of some of the largest heat exchangers ever built for low-temperature processing applications. Because of the low-helium content of the large natural gas volumes processed, there were stringent requirements for essentially complete helium recovery.

The Kerr-McGee plant in Arizona also produces liquid helium. During the past 5 years

the technology of helium liquefaction has more than kept pace with increased requirements. Air Reduction Co., Richmond, Calif., Gardner Cryogenics, Hightstown, N.J., and Linde, Amarillo, Tex., also operate large helium liquefiers. The estimated total capacity of the major commercial helium liquefaction plants is 525 liters an hour. Plans have been announced for a 500-liter-an-hour plant to be completed in Kansas during 1965 (*8*). In addition, many laboratories and development centers have their own small liquefiers. Capacities are a few liters of liquid helium an hour, but from 200 to 300 such liquefiers are distributed throughout the free world.

There are two naturally occurring stable isotopic forms of helium; helium 3 with an atomic mass of 3.0169 and helium 4 with an atomic mass of 4.0038. Helium produced from natural gas is predominately the heavier variety; only 0.00013 mole-percent helium 3 is present. Helium 3 has properties unlike those of helium 4 which make it useful for many scientific investigations at temperatures within a few tenths of a degree of absolute zero. The chief source of helium 3 is Mound Laboratory, Miamisburg, Ohio, which is operated for the Atomic Energy Commission by Monsanto Research Corp. Helium 3 from the laboratory is a product of nuclear reactor technology (*13*).

USES

The Bureau of Mines canvassed its helium customers to obtain information on their use of helium during calendar year 1962. In the period covered by the survey, the Bureau shipped 600 million cubic feet of helium. About 78 percent, or 468 million cubic feet, went directly to Federal agencies, and 22 percent, or 132 million cubic feet, went to non-Federal customers. In addition, the Kerr-McGee plant reportedly sold about 30 million cubic feet to non-Federal customers. Thus, the total helium shipments and assumed use during 1962 was 630 million cubic feet. Total helium consumption in 1962 is summarized in table 3 and compared with consumption in 1955 by non-Federal customers. At that time, the Bureau was the sole quantity producer of helium in the United States.

TABLE 3.—*Utilization of helium in 1962*

Use	Overall use	Federal agency use	Private company use	Private company use on Government contracts	Federal agency use and use on Government contracts	Non-Government use	Private company use in 1955 [1]
Pressurizing, volume-percent	45.0	60.5	0.5	1.0	52.5	--------	[2]
Welding, do	15.0	7.0	38.0	50.0	12.5	30.0	64.5

[5] Total helium use in 1955 was 236 million cubic feet.

Helium is used for pressurizing purposes in liquid-fueled missiles and space vehicles. For boosters, such as Atlas and Titan I, helium provides pressure to push fuel into the pumps that supply the rocket engines. In the Atlas, helium serves an important secondary purpose by filling the thin-skinned fuel tanks, as the fuel is consumed, to provide the rigidity necessary to prevent collapse and failure of the tanks in flight. Helium is also used as a pressurizing medium for testing many of the delicate and intricate piping assemblies and components on which successful launches depend. Development of the large Saturn-class liquid-fueled rocket engines will require increasing volumes of helium for test and operational purposes.

Shielded-arc welding continues to require large volumes of helium and is the largest single

industrial use. In addition to building ships, aircraft, spacecraft, and rocket structures, helium is used in the welding process for items such as food-handling equipment, photographic developing equipment, diesel engine parts, hardware, architectural shapes, and electrical devices, and in the manufacture of many other products made from stainless steel, aluminum, copper, titanium, and zirconium. Much of the helium used for welding is a mixture of 75 percent helium with 25 percent argon.

Helium serves a variety of purposes as a controlled atmosphere. It is used in growing germanium and silicon crystals for transistors, in processing fuels for nuclear energy purposes, and for cooling vacuum furnaces.

In research, helium is used for all the purposes listed in table 3. Other uses include aerodynamic research using helium in wind tunnels and shock tubes, study of adsorption techniques, development of improved seals and valves for positive shutoff, pharmaceutical and biological research, particle physics investigations, development of improved light sources, radiation detection devices, plasma arc studies, mass transfer studies, tensile and impact tests of materials, solid state physics, and development of new techniques for X-ray analysis. Research involving the behavior of materials at temperatures near absolute zero, such as the development of superconducting magnets, requires the use of significant amounts of liquid helium. Some metals and alloys become superconductors at liquid helium temperatures; they offer no resistance to the flow of electricity, and a current once started will flow undiminished as long as the current-carrying material is kept at liquid helium temperature. Superconducting magnets have been built that produce intense magnetic fields at a fraction of the weight and power requirements of conventional magnet systems. Other uses of superconductors may materialize such as in lightweight, efficient power generators and for more efficient long-distance transmission of electric power.

About 35 million cubic feet of helium was used during 1962 as lifting gas. Only two Navy blimps were in service then. These were decommissioned in the fall of the year, and the helium recovered for reuse in other activities. Over half of the 35 million cubic feet was used in balloons to obtain weather information. Most of the remainder was used in balloons that carried special instruments to about 100,000 feet to measure particles entering the earth's atmosphere from space and to make telescopic observations unhindered by the obscuring effects of the earth's atmosphere. The volume used in toy balloons was estimated to be slightly over 1 million cubic feet. Some helium was used in lighter-than-air craft devoted to advertising. The volume of helium used as a lifting gas during 1962 is more than twice the peak helium consumption of 15 million cubic feet for rigid airships during 1930–33.

Use is made of the ease and rapidity with which helium passes through minute openings in detecting leaks or more often in verifying the absence of leaks in a variety of operations and products. Sensitive helium detection devices reportedly can identify helium leaks so small that 3,000 years would be required for a liter of helium to pass through the opening. The method is used to assure freedom from leaks in component parts and piping systems of nuclear reactors, metallic bellows assemblies, electron tubes, hermetically sealed electrical devices, and other items where safe operation or satisfactory service life depend on leakproof characteristics. The relatively large volume of helium used in leak detection exclusively for commercial purposes was primarily to assure a high-quality product.

One of the newer uses for helium is as a carrier gas in chromatography. The principles of chemical analysis by chromatographic means have been known for some time but requirements arising in recent years for higher purity products, more rapid analysis, and greater product yields have stimulated the use of chromatographs in the refining, petrochemical, food processing, drug, and chemical industries. A single chromatograph requires only a small volume of helium annually, but the cumulative effect of a large number of instruments is apparent in the more than 9 million cubic feet used for this purpose.

Another recent use of helium is for heat transfer purposes, primarily in gas-cooled nuclear reactors for power generation. One such reactor near Philadelphia, Pa., is nearing operational status, and others are in the planning stage. Helium does not become radioactive, has good characteristics for removing heat from the nuclear fuel, and reportedly permits better efficiencies by making it possible to operate a reactor at higher temperatures than would be possible with other coolants.

Small, but important, volumes of helium mixed with oxygen continue to be used in the treatment of asthma and other respiratory ailments. Helium is also used as a diluent for anesthetics and as a tracer. Helium-oxygen breathing mixtures have been used by Navy divers for many years because helium is much less soluble in the blood than the nitrogen in normal air mixtures. Recent experiments with high-helium, low-oxygen breathing mixtures hold promise for showing the way for man to live in the sea almost as readily as he now lives on land (*11*, *15*, *19*). Further development of techniques to permit man to work in the ocean

depths would allow exploration and possible exploitation of the vast resources known to lie on or beneath the sea floor.

ALTERNATE MATERIALS

Although few, if any gases have the combination of unique properties that characterize helium, there are applications where substitution is possible. Nitrogen, for instance, may be used for pressurizing liquid oxygen, but at some sacrifice in oxygen quality because of the high solubility of nitrogen in liquid oxygen. Helium, being only slightly soluble in liquid oxygen and other liquids, has little, if any, degrading effect upon them. Consequently, helium is preferred for pressurizing and blanketing operations where reliability and freedom from contamination are of paramount importance.

In shielded-arc welding and other metallurgical processes, helium, argon, or mixtures of the two gases are used to provide an inert gas shield to prevent formation of impurities in the molten metal. For certain welding jobs, the use of helium alone is preferred because welding can be done more rapidly and with less porosity than with other gases. In some instances the higher thermal conductivity of helium offers advantages not possible with argon.

Either hydrogen or helium may be used for inflating balloons and lighter-than-air craft. Hydrogen, being lighter than helium, will provide about 7 percent more "lift" in air but is seldom used in large quantities because of its flammability hazard. This hazard does not exist with helium. Hydrogen may be used instead of helium as the carrier gas in chromatographic analysis equipment. However, in addition to being flammable, hydrogen will combine chemically with the product being analyzed or controlled. Other gases, such as argon, do not provide the sensitivity that is sometimes desired. Helium is preferred as a carrier gas generally because of its inertness and high thermal conductivity.

Carbon dioxide and nitrogen can each be used in gas-cooled nuclear reactors, but helium is preferable. Helium does not corrode the piping, does a better job of transferring heat from the reactor, and does not become radioactive.

In all of the foregoing applications, helium is used primarily because it has some inherent advantage over other materials that might be used. No substitute materials are available in the field of cryogenics, where there is need for temperatures near absolute zero (−459.72° F.). Helium becomes liquid at −452.13° F., a temperature well below the point where all other gases solidify. In fact helium is the only material known that remains liquid at temperatures within a few tenths of a degree of absolute zero.

RESERVES

The presently known or measured helium resource of the United States in helium-bearing natural gas containing three-tenths (0.3) volume-percent or more helium was estimated to be 196 billion cubic feet as of January 1, 1961. Of this volume, probably no more than 154 billion cubic feet can be recovered for use. About 94 percent of the helium resource is contained in the following five helium-bearing gasfields: (1) the Hugoton field of Kansas, Oklahoma, and Texas; (2) the Panhandle field of Texas; (3) the Keyes field of Oklahoma; (4) the Greenwood field of Kansas and Colorado; and (5) the Cliffside field of Texas. The remaining 6 percent is in smaller scattered and isolated fields.

All of the helium-bearing natural gas reserves were discovered by private companies, and most of the reserves are dedicated to supply fuel markets. Consequently, where helium-bearing natural gas is produced without regard for its helium content, the helium, having no value as fuel, is lost.

Helium-bearing natural gas sources available to the five Bureau plants and the five industry plants that recover and sell helium to the Bureau in the helium conservation program represent about 70 percent of the total known helium resource. An additional 20 percent of the total helium resource that could be recovered at costs comparable to present costs is being wasted. The remaining 10 percent is considered a marginal resource, although special circumstances might make recovery of helium economically feasible in specific instances. The effect of such recovery on total helium resource is likely to be small.

Some of the oilfields and gasfields discovered in the past few years in eastern Utah and western Colorado contain helium. However, the helium reserves in these fields are limited, comprising only about 3 percent of the national total. Natural gas production from these fields is also limited, and the resulting wastage of helium amounts to a still smaller percentage of the total annual waste. The prospects for finding new sources of helium comparable with those now known appear poor. The last discovery of a significantly large reserve of helium-bearing gas was in 1943 when the Keyes field in Oklahoma was found.

With the possible exception of the Soviet Union, no country has helium reserves comparable with those in the United States. Canada is the only country in the free world known to produce helium, but the reserves discovered

so far are small compared with those in the United States. Helium-bearing natural gases offer the only presently known economical sources for producing helium. However, there are other occurrences of interest, including gases from mineral springs, fumaroles, and volcanoes; rocks; minerals; certain sands; and meteorites. Helium can also be formed by nuclear bombardment and fusion. It is present in the air in the ratio of about 1 part helium to 200,000 parts air.

CONSERVATION PRACTICES

Conservation in the sense of full and wise use of our Nation's helium resource is the purpose of the Bureau's helium program. Since completion of the Bureau's Keyes, Okla., helium plant in 1959, helium has been in plentiful supply; future supplies are expected to be adequate to meet a threefold increase in annual needs. However, present estimates of continued increased demand for helium will require the purification and sale in the near future of helium obtained from private industry in the long-range helium conservation program.

Although present supplies of helium-bearing natural gas can supply many times the volume of helium presently used each year, these gas supplies, and consequently the Nation's reserves of helium, are limited. Instead of permitting helium resources to be wasted when helium-bearing natural gas is used as fuel, the previously mentioned $47.5 million-a-year conservation program authorized by Congress is in effect to assure that helium is available for use in the future. During the life of the contracts for helium conservation, the Bureau expects to purchase 62.5 billion cubic feet of helium as shown in table 1. Production from Bureau plants is expected to be about 15 billion cubic feet. Thus, the total volume available between 1960 and 1983 is 77.5 billion cubic feet. Demand during the period is expected to be 36 billion cubic feet. The remaining 41.5 billion cubic feet will be stored underground for later use. Use trends for helium indicate growth in annual demand from the present level of 700 million cubic feet to 2,000 million cubic feet by about 1985. Thus, helium placed in underground storage now will be available to augment production from available helium-bearing natural gases when this source can no longer meet annual demand. The present program for helium conservation is expected to meet foreseeable needs beyond the year 2000.

Although extraction of helium from helium-bearing natural gas in advance of burning the gas as fuel is the primary conservation practice in effect today, some users find it economical to salvage helium and repurify it for reuse. Wind tunnel installations using helium for testing models at supersonic velocities were among the first to install equipment for reclaiming helium. Generally, the helium mixed with air or other contaminants is captured in a large bag and then is passed through a low-temperature adsorption process for purification and reuse. Some closed-cycle helium refrigeration systems employ repurification to maintain the high quality of helium in the system. At present the total volume of reclaimed helium is small.

SOURCES OF STATISTICAL INFORMATION

The Bureau's records of its operations are the source of information on occurrence of helium and on the volume of helium produced, shipped, and stored. Estimates of helium end use are obtained through the cooperation of customers. General information on helium produced independently of the Government's program is made available to the Bureau through the cooperation of the private producer.

PRODUCTION AND CONSUMPTION

Helium production from the five Bureau plants in 1963 totaled 774.2 million cubic feet, an increase of 7 percent over the record set in 1961. About 35 million cubic feet of helium was produced by the Kerr-McGee Oil Industries, Inc., plant. Production from Bureau plants since the beginning of operations in 1921 through 1963 was 5.9 billion cubic feet; almost half of this was produced since 1959. Table 4 shows production from 1921 to 1963.

TABLE 4.—*Helium production in the United States*

[Million cubic feet]

Year	Quantity	Year	Quantity
1921–28	[1] 5.8	1960	642.0
1929–42	[1] 11.8	1961	727.1
1943–49	[1] 83.5	1962	683.1
1950–54	[1] 138.0	1963	2,194.0
1955–59	[1] 313.4	Total 1921–63	[2] 7,299.3

[1] Annual average.
[2] Does not include helium produced at the privately owned Kerr-McGee plant but includes helium purchased for conservation.

Conservation helium purchased by the Bureau in 1963 is as follows:

Plant	*Helium delivered (million cubic feet)*
Northern Helex Co	208
Cities Service Helex, Inc	75
National Helium Corp	457
Phillips Petroleum Co., Dumas, Tex	198
Phillips Petroleum Co., Hansford County, Tex	482
Total	1,420

Helium placed in conservation storage from 1960 to 1963 is as follows:

Year	Million cubic feet
1960	273
1961	447
1962	524.6
1963	2,110

Table 5 shows helium consumption in the United States from 1950 to 1963.

TABLE 5.—*Helium consumption in the United States*

[Million cubic feet]

Year	Quantity	Year	Quantity
1950	81	1957	310
1951	109	1958	352
1952	145	1959	375
1953	158	1960	475
1954	190	1961	551
1955	236	1962	630
1956	267	1963	662

The total volume of helium extracted from natural gas during 1963 in the Government's helium program totaled 2,194 million cubic feet. Production from Bureau plants was in excess of demand, and no helium was withdrawn from the conservation supply. The excess production from Bureau plants, 165 million cubic feet, was stored underground. In previous years, the Bureau has stored in the Cliffside field small quantities of helium produced at its plants in excess of market requirements.

Helium shipments from Bureau plants totaled 627.3 million cubic feet. Federal agencies received 473.7 million cubic feet, and 153.6 million cubic feet was sold to non-Federal customers. Table 6 shows Bureau helium shipments. In delivering helium to customers, Bureau plants filled and shipped 1,820 tank cars, 1,212 trailers, and 262,088 standard gas cylinders.

Helium exported by commercial distributors and civilian agencies of the Federal Government in 1962 is shown in table 7. The figures do not include helium used abroad by the defense agencies. Most helium exported to Canada, France, and the United Kingdom was used in atomic energy programs and for experiments at low temperatures. That exported to Japan was used in low-temperature research and for gas chromatography. Helium is exported under licenses issued by the Office of Munitions Control, U.S. Department of State.

STRATEGIC CONSIDERATIONS

The United States is self-sufficient in helium, although total resources are limited and irreplaceable. Helium purification equipment installed at Bureau plants to handle production during seasonal periods of peak supplies of helium-bearing natural gas can be used to augment production by purifying crude helium purchased for conservation. Thus, Bureau plants could, on demand, increase total output of high-purity helium to nearly 850 million cubic feet a year.

Helium placed in underground storage in the long-range conservation program will meet the year-to-year growing demand for helium and assures that large increases in demand could be accommodated on short notice.

TABLE 6.—*Shipments of helium from Bureau of Mines helium plants in 1963*

	Million cubic feet	Percent
Federal agencies:[1]		
Department of Defense	337.3	53.8
Atomic Energy Commission	75.5	12.0
National Aeronautics and Space Administration	52.6	8.4
Weather Bureau	7.8	1.2
Other	.5	.1
Total	473.7	75.5
Non-Federal consumers	153.6	24.5
Total shipments	627.3	100.0

[1] Actual use by the Federal agencies is not reflected by the deliveries shown. The Weather Bureau obtains about as much helium from the Navy as it receives from the Bureau of Mines. The Navy also furnishes helium to the National Aeronautics and Space Administration and Air Force installations.

TABLE 7.—*U.S. exports of helium in 1962*

Country	Thousand cubic feet	Country	Thousand cubic feet
Belgium	108.0	Japan	1,040.0
Canada	3,010.0	Mexico	360.0
Denmark	4.0	Netherlands	14.0
Finland	4.0	Nicaragua	1.0
France	1,327.0	Norway	4.0

Greece	1.0	Sweden	25.0
Guatemala	1.0	Switzerland	289.0
India	1.0	Taiwan	12.0
Israel	77.0	United Kingdom	1,868.0
Italy	76.0		
Jamaica	.5	Total	9,062.0

PRICES

The revised Helium Act (Public Law 86–777) directs agencies of the Federal Government to purchase all major helium requirements from the Secretary of the Interior and provides that helium shall be sold at prices adequate to cover all costs of carrying out provisions of the act, including repayment to the Treasury of the United States, with interest, of all funds that may be borrowed to sustain the program and all capital and retained earnings as of the effective date of the act.

Until November 18, 1961, sales were at prices established in 1954 of $15.50 and $19 a 1,000 cubic feet (f.o.b. plant) for Federal and non-Federal purchasers, respectively. A price to

cover all costs of carrying out the provisions of the Helium Act and to make the prescribed repayments was calculated to be $35 a 1,000 cubic feet. On November 18, 1961, the increased price went into effect and is applicable to all users. Revised regulations, a schedule of charges, and other information on the sale of helium and rental of containers by the Bureau are included in the Code of Federal Regulations (30 CFR 1).

TRANSPORTATION

Over 80 percent of the helium shipped from Bureau plants is delivered to customers in railway tank cars of special design. The rest is delivered in truck semitrailers and standard compressed gas cylinders. Shipments in cylinders by the Bureau are made exclusively from the Amarillo plant. Other Bureau plants ship helium in tank cars and semitrailers. The Navajo plant is about 90 miles from a standard gage railroad. It is connected to a tank car loading facility at Gallup, N. Mex., by a 2-inch high-pressure helium pipeline.

A typical tank car is constructed of 30 steel cylinders, 18 inches in outside diameter and 33 feet long, mounted in a specially constructed frame. Cylinders on the cars are designated ICC 107A (*9*). Permissible filling pressures of individual tank car cylinders range from 1,745 to 4,000 pounds per square inch gage. Cars suitable for filling at the higher pressures will contain about 300,000 cubic feet of helium measured at base conditions of 14.7 pounds per square inch gage and 70° F. (*14*). An empty tank car weighs about 220,000 pounds. The helium in a full car weighs between 2,000 and 3,000 pounds. Freight charges are based on an arbitrarily prescribed minimum carload weight of 40,000 pounds.

Except for a few tank cars owned by other Government agencies, the Bureau's 236 tank cars are the only ones of their kind in use for rail shipment of helium as a compressed gas.

Truck semitrailers are constructed in a manner similar to railway tank cars, but they are smaller and lighter in weight. Tubes for trailers must also meet ICC specifications. The Bureau owns five semitrailers, each having capacity to deliver about 100,000 cubic feet of helium, and two newer trailers that will deliver about 140,000 cubic feet each. The trailers are used primarily in the service of customers whose requirements do not lend themselves to delivery in tank cars. Commercial distributors who purchase helium from the Bureau for resale, a Federal agency, and a contract carrier also own several large-capacity trailers. Smaller trailers, which will deliver from 29,000 to 50,000 cubic feet of helium are owned by the Atomic Energy Commission, the Army, the Navy, and commercial distributors.

Standard helium cylinders hold 213 to 265 cubic feet when filled to 2,000 to 2,400 pounds per square inch gage. The cylinders meet ICC–3A or ICC–3AA specifications. They are shipped in railway boxcars and motortrucks. The Bureau has about 100,000 cylinders for lease to customers, although many users supply their own. An empty cylinder weighs 122 to 137 pounds, and a full cylinder weighs about 2½ pounds more.

The costs of transporting helium as a compressed gas make up a significant part of the delivered price because relatively small amounts of helium can be delivered in proportion to the weight of the container. Recent reductions of 31 percent in the rates for shipment of helium in railway tank cars to the Federal agencies will, at present levels of helium use, save the Federal agencies about $700,000 a year.

A private company has announced plans to transport as liquid the entire production of a proposed private helium liquefaction plant. The plan includes 10,000-gallon tank trailers suitable for transporting liquid helium cross country for subsequent distribution as gas and as liquid (*8*). Ten thousand gallons of liquid helium is equivalent to about 1 million cubic feet of gaseous helium.

The high-purity helium obtained by the purification process or from evaporated liquid may be reduced by contamination from piping and from the containers into which it is eventually put for use. Consequently, where high-purity helium is essential, producers and users alike keep helium handling lines and containers scrupulously clean.

RESEARCH

Until 1961 the Bureau carried on a small research program that was aimed primarily at solving helium production problems and improving processes for the recovery and purification of helium. Research emphasis changed in 1961 and is now directed toward learning more about the properties of helium for the purpose of eventually increasing its utility. Thermodynamic and other data for helium are being reviewed systematically with the objective of identifying "best" values and closing gaps in data by experiments as warranted. Work is underway on projects that include development of a method for measuring the heat capacity of helium and its mixtures with other gases, measurement of the absolute viscosity of helium, diffusion coefficients, the solubility of helium in liquefied gases, and investigation of metastable energy levels in liquid helium. Publication of

research completed at the center includes values for phase equilibria of helium gas mixtures (*5–6, 28–30*) information on the compressibility of gases (*7, 20–21*); continuous analysis of helium in natural gas (*17*); and an apparatus for detecting helium leaks (*18*). A bibliography published in 1952 lists more than 2,600 technical and scientific articles relating to helium (*33*).

Fundamental research on helium is carried on by educational institutions; nonprofit organizations; and Government agencies, such as the National Bureau of Standards, U.S. Atomic Energy Commission, and U.S. Department of Defense. The unusual properties of helium at temperatures near absolute zero continue to be the subject of intensive research despite decades of effort. The results of research on helium are reported regularly, and listings are published in "Chemical Abstracts," "Nuclear Science Abstracts," "Physics Abstracts," Technical Abstract Bulletins," and other abstract services.

OUTLOOK

Although helium is a limited and irreplaceable resource, the long-range helium conservation program carried on by the Department of the Interior assures our Nation a continuing adequate supply for the immediate future and further, has the potential for meeting large-scale requirements for helium well into the 21st century. Fortunately, because of today's far-sighted program, the emphasis on helium can be its wise and effective use rather than measures to lock up the supply for limited use (*31*).

Helium consumption in the United States has increased since 1950 at an average of 20 percent a year. During 1960–64, the rate was 13.5 percent; 475 million cubic feet was used in 1960 compared with about 700 million cubic feet in 1964. Most of the increase was due to the use of helium in the development, testing, and launching of liquid-fueled boosters, such as Atlas and those of the Saturn series. Growth projections made by the Bureau in 1959 indicate that by the year 2000 annual helium consumption will approach 2 billion cubic feet. Experience during the past 5 years agrees well with the 1959 projection. The historic pattern of new applications supplanting old ones is expected to continue, with the effect of broadening the scope of helium uses for scientific, industrial, and defense purposes. Helium to meet these larger demands is expected to be available from the helium-bearing natural gas available for processing at existing extraction plants until about 1985. When helium from this source is no longer adequate to meet annual demand, withdrawal of helium stored underground will begin. As supplies of helium-bearing natural gas decline, reliance must be placed on helium in underground storage. According to present expectations, foreseeable requirements for helium should be met well past the year 2000.

Breakthroughs in science to apply superconductors to long-distance transmission of power and other uses of the low temperatures that can be produced only with helium would require large quantities. Further development of the technology of maintaining artificial atmospheres containing helium to permit man to colonize the sea and develop its riches could require tremendous volumes. These and other uses for helium are near reality today. Tomorrow's new and unforeseen uses could place severe burdens on helium supplies sometime in the 21st century. Then, small isolated sources of helium-bearing gases should become more important and will probably be developed. As these are exhausted, it may become necessary to turn to the atmosphere or to controlled nuclear reactions for helium. Discovery of large new natural sources of helium could change this picture, but based on past experience, the prospects are not good for discovering new sources comparable with those now known in developed gasfields.

As further progress is made in reducing the useless waste of helium into the atmosphere from the burning of helium-bearing gases, and as the economics of doing so are improved, more attention must be given to reclaiming helium for reuse. When these measures are inadequate to assure a continuing supply, some form of end-use controls will surely be required.

PROBLEMS

The overall long-range problem concerning helium continues to be one of rapidly growing helium demand in the face of diminishing helium resources.

More immediate problems concern the cost of transporting helium from the producer to the consumer. Most other gases are or can be produced near the place of use. Helium, on the other hand, occurs in a limited area far from where it is used. Containers for transporting helium as a compressed gas are heavy and hold only 1 or 2 cubic feet of helium for each pound of container. In the past, the high shipping costs have represented a disproportionate part

of the ultimate cost of helium to the consumer. Reduction in freight rates for shipping compressed helium have reduced the delivered cost of helium to the Federal agencies. Nevertheless, as the technology for doing so is improved, the shipment of helium as a liquid may become the more economical method of transportation. Private industry's plans for large-scale transportation of helium as a liquid and the Bureau's studies in the same general area, coupled with reduced freight rates and larger capacity containers for shipping compressed helium gas, offer good prospects of reducing further the delivered cost of helium. Such reductions will be helpful in making helium more readily available to users.

Despite decades of research, there has been no organized systematic effort directed at learning more about the properties of helium. Work by the Bureau is directed toward filling present gaps in the knowledge of helium's properties to increase its utility. Much of the work is extremely difficult, and years may be required to achieve the desired results.

INDIUM

By Harold J. Schroeder [1]

INDIUM commercial applications, beginning only 30 years ago as a dental alloy ingredient, have expanded to uses for engine bearings, corrosion-resistant plating, low-melting alloys, transistors, and many other items.

In 1924, 61 years after indium's discovery, the world supply of the metal could have been held in a teaspoon. Then a silverware firm in the United States became interested in the metal for making nontarnishable silverware and began searching for potential sources. It was first found and extracted from Arizona sphalerite, but later a larger supply was found in zinc-plant flue dusts.

Indium has been found in about 50 minerals, but in concentrates too low for any ore deposit to be mined for indium alone. The zinc mineral sphalerite normally contains trace quantities of indium and is the commercial source of the metal. When zinc and zinc-lead ores are processed, indium, if present, remains in various residues, dusts, or in crude zinc and lead, and after many steps in refining, the metal is recovered for commerical use.

One firm in the United States and another in Canada are the only producers of indium in North America. Indium is also produced in several countries of Europe and in Japan. The United States is the largest indium consumer, and in 1957, the peak year, markets were found for almost 20 tons of domestic and imported indium. The United States resource of indium, obtainable as a byproduct in zinc production, is roughly estimated at 320 short tons.

Indium is used principally in electronic devices, in sleeve bearings, and in special alloys for dental casts, fusible safety plugs and links, and solders.

In 1964 quoted prices of indium metal in stick shapes were $2.40 per troy ounce for 30 to 90 troy ounce lots. High purity grades of indium were available at substantially higher prices.

Research on indium in recent years has been centered on the properties of the element and its compounds for specialized uses in the electronics field and improved methods of producing high purity indium for this purpose.

The outlook for indium is for continued growth in the demand for indium and for productive capability adequate to meet the demand.

BACKGROUND

Indium was discovered in 1863 by Professor Ferdinand Reich and his assistant Theodor Richter in Freiburg, Germany, when spectrographic studies for thallium on a sample of sphalerite revealed some undiscovered indigo-blue lines. The newly discovered element was named indium from the characteristic lines of its spectrum, and late that year the metal was isolated.

In 1924, Oneida Community, Ltd., Oneida, N.Y., became interested in indium to make nontarnishable silverware (*5*).[2] In 1926 William S. Murray, now President of the Indium Corp. of America, Utica, N.Y., led a search and found indium at an abandoned prospect, the Beebe property near Kingman, Ariz. About a thousand tons of ore was mined, and 250 ounces of indium was produced. In 1929 a dependable source of indium was found in the Cottrell dusts of a zinc smelter in Montana, and a recovery method was devised. At about the same time a process to use indium for plating other metals was developed. In 1934 an indium alloy for dentistry was made; this was the first commercial use for the element. Since 1934 both the list of uses and total consumption has grown in importance.

[1] Commodity specialist.

[2] Italicized numbers in parentheses refer to items in the list of references at the end of this chapter.

SIZE AND ORGANIZATION OF THE INDUSTRY

The American Smelting and Refining Company, Perth Amboy, N.J., the only producer of indium in 1964 in the United States, began production about 1940. The Anaconda Company, who also began producing indium about 1940, discontinued production after 1960. A number of other firms have produced small quantities of indium but have discontinued the business due to insufficient demand and high recovery cost.

The Consolidated Mining & Smelting Co. of Canada, Ltd., Trail, British Columbia, has produced indium since 1941, and Cerro de Pasco Corp., La Oroya, Peru, from about 1945 until 1951 when production was discontinued. Production of indium also has been reported in the following countries: West Germany (Duisburger Kuperhütte, Duisburg; Dr. W. Franke, Frankfurt a.M.; and Unterharzer Berg und Hüttenwerke, G.m.b.H., Goslar); Japan (The Dowa Mining Co., Mitsui Mining & Smelting Co.; Mitsubishi Metal Mining Co., Ltd., and Toho Zinc Co.); and the U.S.S.R.

DEFINITION OF TERMS, GRADES, AND SPECIFICATIONS

Indium is a soft, slippery, silvery-white metal and can be deposited on harder metals by rubbing. Some of its other properties are: Density, 7.31 g./cc.; Brinell hardness, 0.9; melting point, 156.6°C; boiling point, 2,075°C; tensile strength, 380 p.s.i.; specific heat, 0.058 cal./g./°C; and crystal structure, face-centered tetragonal (*1*, *10*).

Indium is placed with boron, aluminum, gallium and thallium in Subgroup III B of the periodic table. It displays a valence of both one and three with three being most common. Indium dissolves slowly in cold dilute acids and more readily in hot dilute or concentrated acid; it is not normally reactive with boiling water or alkalies although when finely divided it forms the hydroxide on contact with water.

Indium is usually considered to be nontoxic, but under certain conditions it is toxic (*2*, *11*). Laboratory experiments on toxicity using animals have been conducted. Underskin injections of indium in quantities from 7 to 30 milligrams per kilogram of body weight and venous injections of indium are toxic. Large quantities of indium hydroxide swallowed over a period of 2 weeks are harmful. Acid foodstuffs containing indium from indium-coated containers showed some absorption of the element by the body. Indium citrate of chloride injected under the skin produced intoxication, and degenerative changes occurred in the liver, kidneys, and heart.

TECHNOLOGY

Mineralogy and Occurrence

The earth's crust contains about 0.1 gram of indium per ton, about the same abundance as silver. It is not found free in nature but has been detected in many minerals. No deposits are rich enough to mine for indium alone. Indium has been found in about 50 minerals, some of which are sphalerite, cassiterite, chalcopyrite, coal, galena, hematite, pyrite, and wolframite. In the United States indium is found in very small quantities in various ores of copper, lead, molybdenum, vanadium, and zinc (*3*, *5*).

Indium is most frequently associated with zinc, and as a result commercial recovery is predominately a byproduct in the processing of zinc-bearing ores. In the metallurgy of zinc, indium, if present, may appear in variable proportions in any of the following products: Flue and Cottrell precipitators dusts, residues from zinc retorts, rejects from zinc sulfate solution at lithopone plants, residues from cadmium recovery, lead blast furnace slags and crude zinc and lead.

Extraction

Numerous methods have been used for the extraction of indium from the several smelter products (*4*, *7*, *8*, *9*).

In one process developed for the recovery of indium, zinc oxide fume recovered from lead blast furnace slag is leached with dilute sulfuric acid to remove the bulk of the zinc, leaving indium in the leach residue. After settlement in a thickener, the residue is leached in stronger sulfuric acid to dissolve the indium. After clarification, indium is precipitated from this solution by the addition of zinc oxide and sodium bisulfite. The indium precipitate is washed with water and then leached with strong sodium hydroxide solution followed by a water wash to remove excess caustic. The precipitate is then washed with dilute sulfuric acid to remove residual zinc. The indium precipitate is then dissolved in strong sulfuric acid, and heavy metals are removed with hydrogen sulfide. Aluminum is added to the clarified pure indium sulfate solution to precipitate an indium metal sponge that may be melted and cast into bars of crude metal. Alternatively the sponge may be purified further by dissolving in hydrochloric acid, followed by precipitating the sulfates with barium chloride and the remaining residual heavy metals with hydrogen sulfide. Indium may be recovered by

precipitation with aluminum or by electrolysis of the purified solution. The sponge or cathode metal is melted under a cover of caustic and cast into market shapes.

Another method recovers indium from crude lead containing zinc and indium as impurities. A first step in this process is to treat a molten bath of the crude metal with a suitable chlorine supplying agent to remove the zinc and indium as a chloride slag. This slag is leached with dilute sulfuric acid, and indium is precipitated as a sponge with zinc dust. The zinc-indium sponge is melted, and zinc is removed with chlorine. The crude indium is melted, cast into anodes, and refined electrolytically.

A complex method is employed at one plant to reclaim indium from the insoluble residue produced during leaching zinc oxide for the electrolytic zinc process. This residue is delivered to the lead smelter for the recovery of contained lead and residual zinc. In the lead blast furnaces, the indium enters the lead bullion and the blast-furnace slag in about equal proportions. From the slag, it is recovered along with zinc and lead during slag-fuming. The fume is leached for the recovery of zinc, and indium again remains in the residue, which is retreated in the lead smelter. From the lead bullion, indium is removed in the bullion dross. The dross is re-treated for recovery of copper matte and lead, and in this process a slag is recovered which contains lead, tin, and copper as the major constituents, together with 2.5 to 3.0 percent indium. The dross re-treatment slag is reduced electrothermally to produce a bullion containing lead, tin, indium, and antimony, which is treated electrolytically to yield a high (20 to 25 percent) indium anode slime. The anode slime is treated chemically to give a crude indium metal, which is then refined electrolytically.

In the distillation process of producing zinc, most of the indium remains with the crude zinc and then follows the lead removed as an impurity during refining. The indium is recovered by first cupeling the lead to increase the indium concentration in the resulting litharge product, then leaching with dilute sulfuric acid, and collecting a crude indium sponge by use of zinc slabs. A refined product is obtained by dissolving the crude indium in sulfuric acid, removing impurities by cementation on strips of indium and also on an indium—cadmium—zinc alloy, followed by collection of pure indium sponge on aluminum strips.

Indium can be recovered from old plating solutions. In this process the solution is first evaporated and the organic material destroyed by ignition. The contained silver, lead, copper, cadmium, zinc and nickel are separated from the residue by successively acidifying, filtering out the insolubles, neutralizing the filtrate, and recovering a precipitate of indium, iron, and tin hydroxide. The hydroxides are dissolved in hydrochloric acid, and the indium recovered by electrolysis.

USES

The three largest uses for indium are in semiconductor devices, in bearing alloys, and in special alloys (*1*, *8*).

The largest single use of indium is probably in transistor devices. In the germanium transistor, indium discs or spheres alloyed to each side of a germanium wafer comprises the heart of the device. The indium imparts desirable modification of the electronic properties and equally important it readily wets and alloys with the germanium at a low temperature resulting in easy fabrication, minimal impurity pickup, and absence of contraction strains. Because of these characteristics indium also is used to solder the lead wires to the device. Considerable research and development is underway to utilize indium antimonide, indium arsenide, and indium phosphide in semiconductors of the intermetallic type.

A continuing large use for indium is in sleeve-type bearings where the element gives dependability and long life to heavy-duty and high-speed bearings. It can be plated on or alloyed with silver-lead, copper-lead, and cadmium alloy bearings surfaces to make them harder, stronger, more corrosion resistant, and more retentive of an oil film by increasing wettability.

Indium is used in many special alloys. Despite its softness, small quantities of the metal harden and strengthen aluminum, lead, and beryllium-copper. Lead-indium alloys, highly resistant to corrosion, are used in chemical processing equipment. Low melting indium alloys are used in surgical casts, foundry patterns, and fusible safety-plugs or links. Indium has been used as an oxygen scavenger in gold dental alloys. It increases the tensile strength and ductility of gold and improves its resistance to tarnish. Indium is used as an ingredient in many solders and brazing compounds. Some indium is used in jewelry and silverware alloys to keep metals bright. Indium alloys capable of wetting glass are used in making glass-to-glass or glass-to-metal seals. A silver-indium-cadmium alloy has been used for a nuclear reactor control rod.

Small experimental uses of indium include its use as an additive in gasoline to increase mechanical efficiency and give cooler running engines. It is also used in heavy-duty lubricants. Indium mirrors reflect all colors of the spectrum, and indium foil can be used to detect radioactivity. Batteries smaller than a penny

using a positive terminal of indium were developed for electronic watches that can operate at constant voltage for 2 years. The oxide is used in glass to give colors ranging from canary yellow to tangerine orange. An electric current passed through a tin-bearing indium oxide film on aircraft windshields prevents fogging and icing.

BYPRODUCTS AND COPRODUCT RELATIONSHIPS

Indium supply is dependent on zinc production along with other associated byproducts, such as cadmium, gallium, germanium, and thallium, which are recovered in the reduction of zinc ores.

ALTERNATE MATERIALS

Substitutes for indium to prolong bearing life and combat corrosion are difficult to find. A less costly lead-tin overlay is an alternate to lead-indium bearings, but the antiseizure properties and service are not as good as in lead-indium bearings. The change from piston to jet-driven aircraft eliminates need of any engine bearings and is obviously a factor in indium demand. Extensive research underway in the transistor field could lead to entirely new materials replacing the germanium-indium type of transistor. For some uses, such as in dental alloys and in sealing glass joints, gallium can be substituted for indium; however, gallium is costlier than indium.

RESERVES

The indium content of the measured and indicated zinc reserves in the United States is roughly estimated to be 320 short tons. The content of indium in zinc minerals from different deposits varies widely but an average value of 0.0024 percent indium in zinc concentrates has been used as a guide for approximating world reserves.

SOURCES OF STATISTICAL INFORMATION

Statistical information on indium is limited since the relatively few companies in the world recovering indium do not allow publication of production or shipments data. Data on imports and exports of indium are not available because no separation is made of indium figures from those of other miscellaneous materials.

PRODUCTION, CONSUMPTION, AND TRADE

Markets were found for an estimated 20 tons of domestic and imported indium in the United States in 1957, the peak year. Data on the consumption pattern in the past year, however, is not available. More indium was produced in the United States in 1957 than in any previous year. The Anaconda Company publicized it produced 87,600 troy ounces of indium in 1956. Producers shipments were last published in 1951 and were given as 153,000 troy ounces.

Canadian production is large and in 1957, the last year the figures were published, output was 384,000 troy ounces. Most of Canada's output has been exported to the United States, the United Kingdom, and other European countries. The Peruvian production, discontinued after 1951, amounted to 40,000 troy ounces in 1948 and was mostly exported to the United States.

The tariff on indium metal was decreased from 11 percent to 10.5 percent on June 30, 1958. Indium in concentrate can enter the United States duty-free.

STRATEGIC CONSIDERATION

The United States is the major world consumer of indium. Its current and projected needs are fulfilled by domestic production plus substantial imports, principally from Canada. Indium is not on the Government's list of strategic and critical materials for stockpiling.

PRICES

E&MJ Metal and Mineral Markets quoted the following declining prices per troy ounce of 99.9 percent pure indium: $30 to $15 in 1942, $15 to $10 in 1943, $10 to $7.50 in 1944, $7.50, $4, $3, to $2.25 in 1945, and $2.25 since 1945. In 1958 standard grade indium (99.97 percent) was quoted at $2.25 per troy ounce in small quantities to as low as $1.25 per troy ounce for lots of 5,000 or more ounces.

Effective October 1, 1964, prices for indium metal advanced 15 cents per troy ounce, and the new quotes were $2.40 per troy ounce for 30 to 90 troy ounces for stick shapes; in ingot shapes prices were $1.95 per troy ounce for 100 ounce lots and $1.65 per troy ounce for 10,000 and up lots.

High-purity grades of indium were available at substantially higher prices.

TAXES

No special taxes are imposed on the indium industry. Depletion allowance for domestic producers of indium metal is 15 percent.

RESEARCH

A bibliography of more than a thousand scientific references on indium was published for the period 1863–1958 (*5*).

Research on indium by producers has consisted largely of developing and improving metallurgical recovery processes, investigating the element's properties, expanding old uses, and developing new uses.

The Atomic Energy Commission sponsored research work on the indium isotopes and also on the aqueous chemistry of the element.

Recent research on indium has stressed investigation of properties and techniques in the use of indium for semiconductor and other electronic applications. Companion research has been conducted on methods of producing high-purity indium and its compounds.

OUTLOOK

The outlook is for a continued growth in the demand for indium, particularly in electronic uses. Production capabilities appear adequate to meet the anticipated demand.

PROBLEMS

A major problem is the limited and erratic market for indium, largely caused by the relatively few uses comprising a substantial part of total consumption. There is a need to develop the numerous minor and potential uses of indium.

The paucity of published information on production data, practices and efficiencies hampers determination of the potential productive capacity. In a like manner the absence of consumption data makes a market analysis difficult. From a technologic standpoint there is a need for more data on the corrosion of indium and its alloys in various atmospheres and liquids.

IODINE

By William C. Miller [1]

IODINE was discovered about 150 years ago in solutions leached from the ashes of seaweeds. In 1868, Chile began commercial production of iodine as a byproduct of the nitrate industry. Later it was discovered in California waste oil-well brines and this source now supplies a substantial part of the iodine consumed in the United States.

Iodine occurs in the nitrate deposits of Chile as the minerals lautarite and dietzite. Concentrations of sodium iodate in the nitrate leach solution are treated with sodium bisulfite to precipitate elemental iodine. In California iodine is liberated from oil-well brines by chlorination and blown from the brines by air.

In Michigan iodine is extracted from natural brines by chlorination and blown from the brines by an air-water vapor. In Japan iodine is recovered from brine by the cuprous iodine, electrolytic, or active carbon methods.

The sole domestic producer furnishes about one-fourth of the U.S. requirements. The remainder is imported from Chile and Japan. Iodine and its compounds have many and varied uses in medicine, agriculture, and industry. The use of radioactive iodine in medicine and industry has increased in the past few years. Consumption of iodine is expected to increase owing primarily to expanding use in medicine and pharmacy. The use of iodine as a disinfectant in swimming pools could develop into a sizeable market.

Problems confronting the iodine industry are the lack of data concerning domestic resources, the relatively high cost of producing iodine, and the need for additional markets for iodine and its compounds.

BACKGROUND

Iodine was discovered about 1811 by Bernard Courtois, a potassium nitrate producer. France, unable to obtain from foreign sources the potassium nitrate required for gunpowder, was starting a domestic industry to furnish its requirements. Courtois used crude soda ash obtained from seaweed in his process. He found that an unknown substance introduced with the crude soda ash could be precipitated as a black powder, which yielded a violet vapor when heated. The noted chemist, Gay-Lussac, studied the properties of the powder more intensively and recognized it as a new element. He named it iode, from the Greek word violet color (*5*).[2]

The importance of iodine in medicine was established in 1819 when Dr. Coindent, a Swiss physician, used it as a remedy for goiter. In 1829, wounds were being treated with tincture of iodine. The first application of iodine in the treatment of battle wounds probably occurred during the American Civil War.

By the middle of the 19th century iodine's importance to chemistry was established. Its value was recognized in research and analytical chemistry as a laboratory reagent.

One of the earliest commercial applications of iodine was in 1839 when iodine vapor was utilized as a sensitive material in photography. In 1851 the wet plate process was introduced which used silver iodide (*7*).

For many years the commercial source of iodine continued to be the ashes of seaweed harvested along the coasts of France and Scotland. The seaweed industry declined following 1868 because iodine production from the nitrate deposits in Chile began.

The United States produced some iodine from Pacific coast seaweed during World War I. Recovery of iodine from oil-well brine began in 1928 at a plant in Shreveport, La., and a year later from oil wells in the Signal Hill District of Long Beach, Calif. In 1932 the Louisiana plant was closed and operations moved to California. From 1932 to 1960 U.S. production of iodine was concentrated in California. Iodine from natural brines was produced from wells in the Midland, Mich., area.

[1] Commodity specialist.
[2] Italicized numbers in parentheses refer to items in the list of references at the end of this chapter.

SIZE, ORGANIZATION, AND GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

In the United States, The Dow Chemical Co., the only primary producer, extracts iodine from waste oil-well brines at Seal Beach, Calif., and from natural brines at Midland, Mich. U.S. production supplies about 25 percent of the domestic demand. In addition to Dow Chemical there are 40 domestic firms that convert crude iodine to resublimed iodine or iodine products.

Chile produces a large part of the world's iodine supply from nitrate (caliche) deposits. These deposits are in the provinces of Antofagasta and Tarapacá on the eastern slope of the coast range in a desert area. The Anglo-Lautaro Nitrate Corp., produces about 90 percent of Chile's iodine. The remaining 10 percent is supplied by several small independent producers.

In the Chiba peninsula, east of Tokyo, Japan, iodine is produced from brines associated with natural gas. Six firms extract iodine in significant quantities. Plants of the following companies are on the Chiba peninsula: Aioi Industrial Co., Ltd., Nipp Development Co., Ltd., Nippon Natural Gas Industry Co., Ltd., Ise Chemical Industry Co., Ltd., and Chiba Iodine Co., Ltd. The Daiichi Pharmaceutical Co., Ltd., operates a plant in Niigata Prefecture. Aioi Industrial Co., with two plants, is the largest producer. The iodine industry is represented by the Brine Iodine Association, a Tokyo trade association, reportedly controlled and financed by the Aioi Industrial Co.

Iodine has been recovered from brines in Indonesia, Java, France, England, Germany, and U.S.S.R. and from seaweed along the coasts of Ireland, Scotland, France, Japan, Norway, and U.S.S.R. The Indonesian production facilities previously owned and operated by Dutch firms which exported iodine presumably are now operated by state firms exclusively for domestic needs.

DEFINITION OF TERMS, GRADES, SPECIFICATIONS, AND PROPERTIES

The minimum purity of commercial crude iodine is normally 99 percent; however, much of the commodity is 99.5 percent pure. Crude iodine sold by domestic producers averages 99.8 percent purity. Impurities are chiefly water, sulfuric acid, and insoluble material. The U.S. Pharmacopoeia XIV specifies an iodine content of not less than 99.8 percent. Resublimed iodine is usually 99.9 percent pure.

Iodine is the only halogen that is a solid at room temperature. It is a gray to purplish black crystalline material, melting at 113° C and boiling at 185° C. The element sublimes readily. Iodine is soluble in water, aqueous iodine solutions, solutions of chlorides, bromides and other salts, and many organic solvents. The element is very active chemically, but is normally less violent than other halogens. Iodine is a better electrical conductor than bromine or chlorine. It forms compounds with all of the other elements except the inert gases, sulfur, and selenium. The element reacts with hydrocarbons to form iodo compounds. Iodine adds to unsaturated compounds to form polyiodo compounds.

Iodine and its more concentrated solutions are classed as poisons because of their irritating effects on the gastrointestinal tract and lungs. Maximum safe concentration for short exposure is set at 0.5 to 0.1 ppm, and at 0.1 ppm for prolonged exposure (*7*).

TECHNOLOGY

Iodine is widely distributed, occuring in small quantities in rocks, soils, brines, and sea water. It occurs in about a dozen different minerals, the most important being lautarite [$Ca(IO_3)_2$], and dietzite ($7CaI_2O_6 \cdot 8CaCrO_4$). Iodine has been recovered commercially from salt deposits, seaweed, and from natural and oil-well brines and brines associated with natural gas.

In Chile, iodine occurs in the caliche or nitrate deposits as the minerals lautarite and dietzite. The iodine content of the deposit ranges up to 0.3 percent; however, the average crude caliche ore contains 0.03 to 0.05 percent iodine in the form of iodates of calcium, potassium, and sodium.

The iodate compounds are dissolved with the nitrate in either the Shanks or the Guggenheim methods used in the processing of the caliche ores. The iodates gradually build up in the mother liquor to a concentration of between 5 and 10 grams per liter of iodine. To recover the iodine a portion of the leach solution is drawn off intermittently and treated with sodium bisulfite to reduce the iodate to iodine. Next an exactly calculated volume of the mother liquor is added and solid iodine is precipitated. The iodine is filtered, washed, pressed into cakes, sublimed in iron retorts, and collected from ceramic condensers in the form of purple-black crystals averaging about 99.6 percent in purity. Iodine recovery plants are operated in such a way as to balance production against expected

sale volume, because their productive capacity exceeds demand (*1*).

In the United States, iodine occurs in oil-well brines of the Los Angeles basin, California and the natural brines of the Midland area, Michigan.

The brines of the Los Angeles basin average about 65 ppm iodine (*7*). The extraction process used by the Dow Chemical Co. is continuous. The brine is acidified with sulfuric acid, treated with chlorine, and pumped to a tower where the iodine is blown out by a countercurrent of air. The iodine vapor is absorbed in a solution of hydroiodic and sulfuric acid and treated with sulfuric dioxide to reduce the iodine to hydroiodic acid. Part of the solution is drawn off and chlorinated to precipitate iodine which is filtered off. It is then melted in a kettle under concentrated sulfuric acid and cast into pigs.

Brines of the Midland area have about one-half of the concentration of the oil-well brines of California. The extraction process for lean iodine brines is similar to the process used for stronger brines and is part of an overall operation that recovers a variety of other products. The brine is acidified with hydrochloric acid and then chlorine is added to partially oxidize the iodine to its elemental form. The oxidized brine enters the top of an iodine desorption tower where the solution moving down the tower is stripped of iodine by a countercurrent stream of air and water vapor. Additional amounts of iodine are formed by the reaction of residual iodine and the ferric ion in the brine as the solution passes through the tower. From the desorption tower the brine goes to other recovery processes. Sulfur dioxide is added to the water-vapor and air phase to reduce the free iodine to the more easily recovered hydrogen iodine form before vapor enters a hydrogen iodine absorber. In the absorber tower, hydriodic and sulfuric acids are added to absorb the hydrogen iodine contained in the carrier gas. From the tower the absorber liquor goes to a batch chlorinator where the iodine is precipitated as crude iodine and is separated from the liquor by filtration. To purify the crude iodine it is melted at about 250° F under a layer of concentrated sulfuric acid. Organic contaminants are decomposed and water is removed by the hot acid (*4*).

In Japan, brines associated with natural gas have replaced seaweed as the principal source of iodine. The brines occur in three sandy strata, underlying the Chiba peninsula, that range in thickness from 625 to 1,640 feet and contain about 25 percent brine.

In the three methods employed to extract the iodine from the brines, the natural gas is removed from the brines at the beginning of the process. In each method the gas is used in the final stage to resublimate the iodine. One method is to introduce iron sulfate and copper sulfate into the brine to produce copper iodide. The iodide is oxidized to yield crude iodine. In another method sulfuric acid is mixed with the brine to yield chlorine gas. To the resultant solution, sodium nitrate is added to precipitate crude iodine which is absorbed by inactive carbon. The crude iodine is dissolved in hot sodium hydroxide and then treated with sodium nitrate and chlorine gas to precipitate refined iodine. In the third method the electrolysis of a mixture of brine and sulfuric acid produces crude iodine. Activated carbon is utilized to absorb the iodine. To refine the crude iodine, the same procedure used by the preceding method is employed.

Iodine has been recovered from seaweed, which extracts it selectively from sea water. In one process, kelp was leached with water and the resulting mother liquor treated with sulfuric acid and manganese dioxide to release iodine. Other processes involved leaching a portion of the iodine by washing fresh seaweed with water and inoculating the slurry with bacteria to cause fermentation. The resulting solution was neutralized with lime, filtered, and evaporated to obtain iodine.

USES

Iodine and iodine compounds have numerous and various uses in medicine, agriculture, and industry. More than half of the iodine consumed is used in medicines and antiseptics. Probably the best known is the household antiseptic, "tincture of iodine." Iodophors, mixture of iodine and organic carriers, are being used increasingly as antiseptics and disinfectants. Iodine and its compounds are used for disinfecting drinking water. Another application is in iodized salt, which contains about 1 part of potassium iodide to 10,000 parts of salt. Silver iodide crystals have been used to seed clouds thereby inducing rainfall. Iodine is essential for the health of man and animals, inasmuch as it promotes the production of thyroxin in the body and thereby prevents goiter. Potassium or sodium iodide, potassium iodate or cuprous iodide are often added to livestock feed. Iodized proteins in stock and fowl feeds prevent various diseases and increase the yield of milk and eggs. Iodine is used in X-ray contrast mediums and in a radioactive isotope (I–131) as a diagnostic aid in examinations of the human body. Radioactive iodine is also used for physical therapy. Iodine–131 is being used in increasing quantities in industry to con-

trol processes and for research. Iodine compounds are used extensively in wet-plate photoengraving and in photographic film emulsions and developers. An expanding use in metallurgy is in the production of high purity metals such as titanium, silicon, hafnium, and zirconium (*9*). In addition, iodine has many other uses in metallurgy, rubber, dyes, analytical reagents, and as catalysts. Potassium iodide has been shown to be an effective disinfectant for swimming pool water which could develop into an important market (*2*).

BYPRODUCTS AND COPRODUCT RELATIONSHIPS

In Chile iodine is recovered as a byproduct of the nitrate industry. Production of iodine is controlled by economic conditions and policies affecting the nitrate industry. In the United States, iodine is obtained as a byproduct of the oil industry and as a coproduct of natural brines. Concentrated liquors from a plant adjoining Searles Lake, Calif., have a relatively high iodine content. Production of iodine from this source may became commercially feasible. In Japan, natural gas is obtained as a coproduct in the production of iodine. The gas is used in the resublimation of the iodine, but some is discarded.

ALTERNATE MATERIALS

Iodine and iodine compounds are relatively high priced commodities whereas other less expensive halogens, such as chlorine or bromine, are substituted where feasible. Some substitutes for iodine compounds used as antiseptics are mercurochrome and antibiotics.

SECONDARY SOURCES AND RECOVERY

In most applications iodine and iodine compounds are consumed in such a way that it is impractical to recover them. Some iodine is recovered in industrial processes, but this quantity is small. At this time secondary recovery is considered an unimportant factor in the economic picture.

RESERVES

Indicated reserves and potential future resources of iodine in domestic oilfield and natural brines are large but have not been adequately measured. Concentration of iodine in oilfield brines near Shreveport, La., averages about 35 ppm and in the Los Angeles basin of California ranges from 60 to 70 ppm. In the natural brines of the Midland, Mich. area the cencentration of iodine is about 35 ppm.

There are large resources of iodine in foreign countries. An estimate of the indicated reserve of Chilean nitrate minerals from which iodine is obtained as a byproduct is about 1 billion tons. The run of mine iodine content of these minerals is about 0.04 percent.

Natural-gas-well brines of Japan are reported to contain about 500,000 tons of iodine. Unmeasured quantities of iodine are contained in brines in Indonesia, Italy, East and West Germany, France, England, and U.S.S.R., as well as saline well water in Java and various coals in West Germany. Seaweed found along the coasts of Ireland, Scotland, France, Japan, Norway, and U.S.S.R. can be considered as a potential reserve.

CONSERVATION

Development of a more efficient recovery method to obtain iodine from Michigan brines with low-iodine concentrations utilizes a portion of a natural resource previously wasted.

In Chile, much of the iodine in the nitrate leach solution is eventually discarded. This iodine could be recovered if there were a larger market.

In some metallurgical processes iodine is recovered and reused. Recent developments in the medical and pharmaceutical fields show a trend toward the use of more efficient preparations having lower iodine contents.

SOURCES OF STATISTICAL INFORMATION

Bureau of Mines obtains data from industry on production and consumption of crude iodine and iodine products. The Bureau also compiles foreign trade data from the Bureau of the Census. Statistical information is published in the Minerals Yearbook and in other statistical and technical publications.

PRODUCTION, CONSUMPTION, AND TRADE

Domestic recovery of iodine from well brines was started in 1928 near Shreveport, La., and in 1929 iodine was extracted from oil-well brines at Long Beach, Calif. Output from the Los Angeles basin area had a pronounced effect on the American market, and by 1936 the price had dropped to an alltime low. Domestic iodine recovery increased slowly after World War II

reaching a peak in 1952. Thereafter output decreased slightly until 1957 and 1958, when it decreased noticeably owing to the sharp drop in the price of crude iodine. In 1960 Dow Chemical became the sole domestic producer. Production was concentrated in California until 1961 when Dow Chemical started production from the natural brines of Michigan. In 1963 increased production capacity for extracting iodine from the natural brines shifted 53 percent of the production to Michigan.

Most iodine consumed in the United States is in the form of iodine compounds. The principal compounds are potassium and sodium iodide although many other inorganic and organic compounds are consumed as shown in table 1. Most crude iodine is resublimed to greater purity or converted to iodine compounds.

The United States imports a large portion of the iodine consumed from Chile and Japan in the form of crude iodine as shown in table 2. Production of crude iodine in Chile is shown in table 3. Large stocks of iodine are held by producers in Chile and by importers near New York City. The latter stocks are replenished at irregular intervals as they become depleted by withdrawal for domestic consumption and small export requirements.

Crude iodine is admitted free of duty under U.S. tariff laws. A charge of 10 cents per pound is levied on resublimed iodine and 25 cents per pound on potassium iodide.

TABLE 1.—*Crude iodine consumed in the United States*

Compound manufactured	1959–61 (average)			1962			1963

STRATEGIC CONSIDERATIONS AND GOVERNMENT PROGRAMS

In the United States the only domestic producer supplies about one-fourth of the requirements. Production could be expanded to provide for increased domestic needs, but not for an emergency. Chilean producers could provide ample supplies during an emergency, but the long shipment by water could become critical during wartime.

Iodine, an essential commodity during a war, is stockpiled by the U.S. Government. The basic stockpile goal was completed March 31, 1959. An increase in the stockpile objective was announced in March 1964. On June 30, 1964, Government inventories totaled 4.3 million pounds, of which 3.0 million was in the national (strategic) stockpile, 0.3 million in Commodity Credit Corp. stocks, and 1.0 million in the supplemental stockpile.

PRICES AND COSTS

For many years crude iodine sold for $4 per pound at New York City in accordance with prices established by the Chilean Producers' Association. Prices were reduced after 1931 owing to competition from iodine recovered from California waste oil-well brines. On October 10, 1936, crude iodine sold for 81 cents per pound in New York City. In 1942, the Office of Price Administration placed a ceiling price of $1.28¼ per pound on crude iodine (150-lb. kegs). On November 10, 1946, the ceiling price on crude iodine was removed and the price rose to $1.42½ per pound. According to the Oil, Paint and Drug Reporter, prices during 1963 were as follows:

	January through August	September through December
Crude iodine, in kegs, per pound	$1.10	$1.18
Resublimed iodine, United States Pharmacopoeia (U.S.P.), bottles, drums, do	2.20–2.22	2.20–2.22
Ammonium iodine, National Formulary (N.F.), 25-pound jars, do	4.51	4.51
Calcium iodide, 25-pound jars, do	4.27	4.27
Potassium iodide, U.S.P. drums:		
500 pounds or more, do	1.15–1.55	
Over 500 pounds, do		1.15
Under 500 pounds, do		1.20–1.55
Sodium iodide, U.S.P., 300-pound drums, do	2.13	2.13

TAXES

The U.S. income tax law grants iodine producers, domestic and foreign, a percentage depletion allowance of 15 percent of gross income not to exceed 50 percent of the net income without depletion deduction.

TRANSPORTATION

Cardboard containers, lined with Saran plastic, are used to ship domestic crude iodine. Each container holds 200 pounds of crushed crystalline iodine. Iodine is shipped by train or truck to warehouses in St. Louis, Mo., or New York, N.Y. There is no specific freight classification; it is shipped as "Chemicals, not otherwise indexed by name (n.o.i.b.n.)" and requires no special label. Resublimed iodine is also shipped in cardboard containers, in 25-pound glass jars, and in ¼-, 1-, and 5-pound bottles.

RESEARCH

Research has been done on various aspects of iodine by the iodine industry and research institutions. The Chilean Iodine Educational Bureau, Inc., 120 Broadway, New York, N.Y., has made numerous grants for exploring the advantages of iodine over other halogens as a disinfectant for swimming pool water (*2*). The Bureau of Mines has conducted research on fundamental properties of iodine and on its use in metallurgy.

OUTLOOK

The short-term outlook for domestic production of iodine is for a continued yearly increase. Although the dwindling production of iodine from the oil-well brines of California will concentrate the domestic production of iodine from the brines in the Midland, Mich., area; production from the oil-well brines is expected to continue for several years. Domestic production could not supply an adequate quantity of crude iodine if a very sharp increase in the demand for iodine occurs. The long-term outlook for domestic production is problematical because accurate estimates of iodine reserves are not available. Extraction of iodine from the brines

of Searles Lake, Calif., brines from other areas in Michigan other than Midland, and from sea water may provide potential future resources.

Both the short- and long-term outlook for iodine consumption in the United States is for a steadily increasing commercial use of iodine preparations as disinfecting and sanitizing agents. The use of iodine as an antiseptic and disinfectant will increase because of the growth in population and the additional approval given by Federal, State, and local organizations. Iodophors and diatomic iodine solutions are used as water purifyers in hospitals and restaurants, and as disinfectants in dairies. A prediction was made that the total number of swimming pools would increase by 15 percent by the end of 1964 and that by 1975 there will be approximately 1 million swimming pools in the United States. The treatment of swimming pool water with iodine may develop into an important commercial application for iodine compounds. Advances in process technology and a price level which is more favorably competitive with other halogens, especially chlorine, could result in increasing the consumption of iodine for industrial applications. Increasing use of radioactive iodine in medicine and industry can be expected.

PROBLEMS

Domestic iodine operations are hampered by relatively high costs compared with the foreign areas that supply major tonnages to the present market.

The lack of domestic iodine reserve data prevents firm evaluation of long-range and emergency production potential.

The relatively high cost of producing iodine is a deterrent to its wider utilization. The iodine industry is confronted with the lack of a market commensurate with the production potential.

More detailed statistical and economic data are needed for evaluation of market potential.

Lack of sufficient information on the physical and chemical properties of iodine and its compounds retards the development of new markets.

The principal domestic iodine recovery method makes discarded brine unsuitable for recharging oil-bearing rock strata.

IRON

By Horace T. Reno [1]

THE IRON ore industry of the United States grew from an annual output of less than 5 million tons in 1870 to over 115 million tons annually in 1951. Since 1951, annual output measured in terms of usable ore shipped to the consumer has declined to about 80 million tons a year, but the industry has continued to grow in terms of capital invested and crude ore mined. There have been sweeping changes in almost every facet of the iron ore industry since World War II when the domestic industry ceased to be the sole source of ore and mining of low-grade magnetite taconite deposits was started in the Lake Superior district.

Sixty-eight countries of the world reported iron ore production in 1963, and more than 150 million tons of iron ore was sold outside the country of origin in 1962.

Sedimentary hematite deposits of primary origin, hematite and magnetite deposits of complex origin, and replacement vein deposits have been the most productive commercial iron deposits to date. However, Precambrian metamorphosed sediments, such as taconite deposits of Minnesota, the jaspilite deposits of Michigan, and the specular hematite and magnetite bearing iron formations which comprise the southern ranges of the Labrador-Quebec district are the principal type of deposits to be newly exploited in the last decade.

Open-pit mines produce approximately 90 percent of the iron ore in the United States because the cost of underground mining precludes expending funds for beneficiation to meet stringent market requirements.

Iron ores are beneficiated by crushing, sizing, washing, concentrating, and agglomerating. Concentration is accomplished by washing, by gravity separation in jigs, heavy-media cyclones, or Humphrey spirals, by magnetic separators, or by flotation. The ores are agglomerated principally by pelletizing at or near the mines and by sintering with other material at steel mills.

Blast furnaces have proved to be the most efficient tool for smelting iron ore and are used to smelt more than 93 percent of the iron ore consumed in the United States. Small furnaces have proved uneconomic principally because of the cost of labor. Coke is the most expensive material and the largest single cost item in iron ore smelting. Methods have been devised to save coke by injecting various gases, oils, and powdered coals into the smelting zone of the furnace.

Sponge iron processes in which the ore is reduced at temperatures below the fusion point of iron, and direct iron processes in which the ore is reduced at temperatures slightly higher than the fusion point, present possible alternative methods for producing iron, but they have been found to be applicable only in specific economic and physical environments. They are not used in this country because they cannot compete in production costs with blast furnaces.

Iron ore resources are reasonably well distributed around the world and unquestionably are sufficient for centuries. The United States uses between 120 and 125 million tons or more of iron ore a year. Most of it is smelted to produce iron, but small quantities are used in making cement, special high-density concrete, and pigments, and magnetite concentrate is used for the heavy-medium in coal processing plants.

Iron is obtained as a coproduct or byproduct in smelting copper, lead, zinc, and nickel sulfides and is a coproduct in mining and treating titanium minerals. The supply of scrap iron and steel fluctuates directly with the demand. Unrecoverable iron losses from the mines through the complete cycle of use to return scrap range from 16 to 31 percent.

The United States emerged from the era of peacetime self-sufficiency and high-grade iron ore in the latter part of the 1940's. In an emergency, however, the United States could be self-sufficient for 2 or 3 years.

[1] Commodity specialist.

Available iron statistical data present adequate coverage of the iron ore industry through the blast furnace. Industry, some States, educational institutions, and the Federal Bureau of Mines are conducting comprehensive iron ore research programs.

The outlook for the iron ore industry throughout the world is that the long-term trend in the price of iron ore in terms of constant value dollars will be downward, and that government actions will not influence the industry adversely. U.S. production for internal consumption will be 80 million tons of 60 percent iron ore by 1970 and 92 million tons by 1980. In addition 5 to 10 million tons will be produced for export. The principal iron mines of the world producing for international trade will have capacity to produce about 300 million tons of high-grade iron ore annually by 1980.

The principal problem of the domestic iron ore industry is to meet both price and quality competition from foreign producers.

BACKGROUND

The iron ore industry of the United States is almost three and one-half centuries old. High-grade ore was produced in the Colonies and smelted in charcoal reduction plants distributed from Georgia to New Hampshire. Incomplete records indicate that less than 50 million tons was mined through 1870. The industry grew from an annual output of less than 5 million tons in 1870 to more than 50 million tons annually by 1910; it was producing 75 million tons annually by 1916, 100 million tons annually by 1942, and over 115 million tons by 1951. Since then the annual output of usable ore has declined to less than 80 million tons, but in terms of capital invested and crude ore mined the industry has continued to grow.

Discovery of the Lake Superior iron mining district and development of the Bessemer steelmaking furnace in the 1850's and the smelting industry's change from charcoal to coal and then to coke in 1875 consolidated iron ore mining and smelting. In the same period, development of the Great Lakes transportation system led to establishment of the world's foremost iron and steel complex in the bituminous coal region of Pennsylvania, Ohio, West Virginia, and Illinois. Iron and steel plants based on local ores were established in Alabama, New York, New Jersey, Tennessee, and Colorado, but the Lake Superior district has accounted for about 80 percent of the iron ore mined in the United States.

Until the end of World War II, the domestic iron-ore mining industry was virtually the sole source of iron ore for the United States. Enriched ores of the Lake Superior district that contained 50 to 55 percent iron, were the accepted standard of high quality by which other ores were gaged. In fact, the industry was little changed from the pattern established 75 years before. The end of the war, however, marked two significant changes: First, the industry ceased to be the sole source of ore for the United States and second, mining of low-grade magnetic taconite deposits was started in the Lake Superior district. As a result there have been sweeping changes in almost every facet of the iron ore industry. Foreign iron ore deposits supply about a third of U.S. needs for ore. Iron ore pellets, a processed product containing at least 63 percent iron, have become the standard of high quality. Most domestic underground iron mines have been shut down and open-pit iron mining has changed from a seasonal to a year-round operation. Only the Great Lakes transportation system and the preeminence of the Lake Superior district remain of the prewar iron mining industrial pattern.

SIZE, ORGANIZATION, AND GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

Each year, the iron ore industry produces more than 500 pounds of iron ore for every person in the United States. In 1963, iron ore accounted for more than one-third the value of all the country's metal production. More than 21,000 men were employed directly in the industry; investment per man directly employed has exceeded $100,000 if the costs of transportation facilities are included in the total.

There were 179 iron mines in the United States in 1963; 31 of these produced more than 1 million tons each and together they produced 78 percent of the crude ore and 71 percent of the usable ore; 23 mines produced more than 500,000 tons; 61 produced more than 100,000 tons and the remaining 64 produced less than 100,000 tons. Integrated iron and steel companies control 70 to 80 percent of the domestic iron ore output. Several of the larger of these companies control or have an interest in iron mines in Canada, Chile, Liberia, Peru, and Venezuela.

Sixty-eight countries of the world reported iron ore production in 1963, but 10 countries produced four-fifths of the total. The U.S.S.R. was the leading producer, followed by the United States, France, China, Canada, Sweden, United Kingdom, India, West Germany, and Venezuela in that order.

International trade in iron ore is a large and growing business. In 1962, more than 150 million tons of iron was sold in the world markets outside the country of origin. Conservatively, this ore was valued at the port of export at more than $1 billion. That same year, 19 countries exported more than 1 million tons of ore. Measured by iron content, Canada, shipping mostly to the United States, was the principal exporter, closely followed by Sweden, shipping to Western European countries, and the U.S.S.R., shipping to its satelites. Australia and some of the smaller countries on the west coast of Africa are rapidly expanding their capacity to produce iron ore for export. If world trade in iron ore expands at the growth rate of the last 5 years, it will be more than doubled by 1980.

The Lake Superior district (Michigan, Minnesota, and Wisconsin) accounted for 77 percent of the crude and usable ore produced domestically in 1963; the Northeastern district (New Jersey, New York, and Pennsylvania) accounted for 7 percent of the crude and usable ore; the Western States (Arkansas, Idaho, Missouri, Montana, Nevada, New Mexico, Utah, and Wyoming) accounted for 5 percent of the crude and 6 percent of the usable ore; the Southeastern States (Alabama and Georgia) accounted for 4 percent of the crude ore and 3 percent of the usable ore; and Tennessee, Arizona, Arkansas, California, Colorado, New Mexico, and Texas accounted for 6 percent of the crude and 7 percent of the usable ore. Distribution of iron blast furnaces in the United States is given in table 1.

DEFINITION OF TERMS, GRADES, AND SPECIFICATIONS

Iron ore is classified according to the principal mineral constituent as either hematite, magnetite, or limonite (brown ore). In the Southeastern district hematite ore is called red ore. The term "natural ore" is used to designate iron ore that contains moisture, in contrast to "dry ore" that has been dried but not calcined. Iron ore is measured in long (gross) tons to the blast furnace, but pig iron, the blast furnace product, is measured in short (net) tons.

Iron ores are described as crude or usable. Crude ore is the material, as mined, prior to any processing for removing waste constituents, though it may be crushed and screened. Usable ore is the product of mine, beneficiating, or

agglomerating plant which is shipped without further processing to the consumer. In this category are included direct-shipping ore (the usable ore as mined), iron ore concentrate (ore from which waste constituents have been removed), and iron ore agglomerate (compact masses of either ore or fine-grained concentrate).

Beneficiated ores are usable ores that have been treated to improve either their physical or chemical characteristics. Thus ores that have been improved by simple sizing or crushing are among the beneficiated ores.

Grades of iron ore are established according to percentage and type of impurities and by physical characteristics; within limits, the percentage of iron is a secondary consideration. Iron ore delivered to Lake Erie ports is purchased on the basis of 51.5 percent iron; usable iron ore shipped in the Southeastern district in 1958 contained an average of 39 percent iron.

The five principal grades of iron ore are—(1) bessemer, containing not over 0.045 percent phosphorus; (2) low-phosphorous, nonbessemer, containing between 0.045 and 0.180 percent phosphorus; (3) high-phosphorous, containing over 0.180 percent phosphorus; (4) manganiferous, containing over 2 percent manganese; and (5) siliceous, containing over 18 percent silica. In addition, iron ore is often described as lump, fine, high sulfur, high silica or titaniferous. Buyers' specifications are rigid within the above named grades, and maximum impurity limits are always cited.

TECHNOLOGY

Geology

The iron content of the earth's crust has been calculated at 5.06 percent (*13*).[2] A fractional part of this iron has been concentrated, under varying geologic conditions, into widely distributed, multi-origin deposits formed in many rock types. Of the various commercial deposits, the most productive to date have been: (1) sedimentary hematitic deposits of primary ore enriched by weathering processes; (2) hematite and magnetite deposits of complex origin in metamorphic rocks; and (3) replacement and vein deposits.

Limonite, siderite, hematite, and magnetite are the principal iron-ore minerals. In sedimentary deposits these minerals have been deposited mechanically, chemically, or biochemically; the mineral species have been governed by the conditions of deposition. The iron was derived from weathering of igneous minerals such as hornblende, pyroxene, or mica. Silicate, aluminate, and carbonate minerals, and iron and titanium mineral combinations thereof are common gangue.

Precambrian metamorphosed sediments comprise a major part of the world's low-grade iron-ore deposits. They were exploited first in Lake Superior district after World War II as a result of (1) imminent depletion of high-grade deposits, (2) growing demand for iron, and (3) development of more efficient mining and beneficiation techniques. The taconite deposits of Minnesota in which magnetite is the principal iron mineral and the jaspilite deposits of Michigan in which specular-hematite is the principal iron mineral have been proved commercial sources of iron only since 1954. The success of the mining companies exploiting these deposits, and the demand for the iron-ore pellets produced from them influenced others in the iron ore industry to prospect for and develop similar deposits. Precambrian metamorphosed specular-hematite and magnetite bearing iron formations which comprise the southern ranges of Labrador-Quebec district in Canada have been developed on a large scale in the last decade, and similar deposits have been developed recently in the Western United States and in the U.S.S.R.

Titaniferous iron deposits of sedimentary metamorphic, and magmatic origin are prevalent throughout the world, but few are exploited where other type iron deposits are available.

Mining

Open-pit mines produce approximately 90 percent of the iron ore in the United States. The trend has been toward more open-pit mining and less underground mining because improvements in excavating equipment has permitted a steady increase in the overburden-to-ore ratio since World War II. In the last 5 years, however, underground mining has been decreasing steadily because the average ore as mined underground would not meet rigid market specifications, and the cost of underground mining precluded expending funds for beneficiation. Underground mines produced approximately 15 million tons of ore in 1963. It is significant that only 16 million tons of direct-shipping ore was produced in 1963.

Open-Pit Mining

Mining methods in open-pit iron mines are similar but vary widely in detail. Overburden is stripped with power shovels, draglines, or scrapers, and is transported either by rail, trucks, conveyor belts, skips, or in the scrapers. The overburden on shallow, thin-bedded deposits often is double or triple cast with a dragline excavator. The choice of equipment is

[2] Italicized numbers in parentheses refer to items in the list of references at the end of this chapter.

controlled by the physical characteristics of the overburden, the depth and size of the ore body, and the nature of surrounding terrain.

In large pits, ore is loaded exclusively with power shovels, but in some thin-bedded deposits it is loaded with dragline excavators. Ore is transported from the pits by rail, trucks, skips, conveyor belts, or by combinations thereof; the choice with few exceptions is ruled by the grade of haul and the size of operation.

Drilling equipment used in large, open-pit iron mines includes churn drills, rotary drills, down-the-hole drills, jet-piercing apparatus, and air-driven percussion drills. Jackhammers and wagon drills are used in the smaller mines. Churn drills predominate in the Lake Superior district's soft residual-hematite mines, and jet-piercing apparatus predominates in taconite and jaspilite mines. However, roller-cone rotary drills and down-the-hole drills with tungsten-carbide-insert cutting edges have proved superior to churn drills and to jet-piercing equipment in some types of ground.

Mining benches in open-pit mines range in height from 20 to 50 feet; the average is about 35 feet. Drill holes spacing and burden (distance from first line of holes to face) range from 12 to 30 feet. Hole sizes range from 5 to 12 inches. Jet-piercing apparatus make an uneven diameter hole ranging in size from 8 to 20 inches or more. The usual practice is to take advantage of the flexibility to chamber the bottom or various depths of the hole to obtain the most efficient blasting. Field-mixed ammonium nitrate and fuel oil is now the most common explosive used in open-pit iron mines where moisture is not a problem. Waterproof free-flowing low-velocity blasting powders are used in wet ground. Some form of delay detonation is used in all except the smallest open-pit iron mines.

Underground Mining

There has been a concerted effort since 1960 to improve the efficiency and lower the cost of underground iron mining. Raise boring machines, a hard rock mole that drives 7-foot diameter openings, and continuous miners similar to coal mining machines have been used successfully. The larger underground mines have been mechanized to the same extent as the open-pit mines and wherever possible loaders, trammers, conveyors, samplers, and hoists have been fully automated. Closed circuit television is used to monitor isolated operations. These practices have stimulated the underground miners to modify and vary mining methods to the point where conventional nomenclature no longer completely describes the operation.

Sublevel caving has been the principal underground method of mining iron ore in the Lake Superior district. Block and panel caving and variations thereof are used in large ore bodies where dilution is not a problem. Shrinkage stoping, open stoping, sublevel stoping, with many modifications and various other methods also are used depending on the size, shape, and character of the orebody, and the character of the enclosing rocks. Most bedded deposits are mined by room and pillar methods similar to those used in coal mining. Air-driven percussion and auger drills and electric driven auger drills are used in underground iron mines. Drifters on jumbos are used in large headings, jack-leg hammers in small headings, and jack-leg and stopers in stopes and raises. Long holes are drilled with air-driven drifters and rotary machines with auger-type drilling strings.

Ammonium nitrate and fuel oil, ammonium nitrate-TNT slurries, and gelatin dynamites are used in blasting underground. Cap and fuse regular delay and fast delay caps are used for detonation. Slushers are the principal means of loading. Room and pillar mines use conventional metal mine mechanical loaders and some coal loaders. Ore is transported underground on rails, on conveyor belts, and with trackless haulage units.

Beneficiation (30, 38)

Beneficiate, as applied to iron ore, is a broad general term that includes any process used to improve physical or chemical characteristics of the ore, that is any process used to increase the value of the ore after it is mined, but before it is smelted. Thus crushing, sizing, washing, concentrating and agglomerating are processes of beneficiation.

Crushing, Sizing, Washing, and Concentrating

High-grade, hard lump ores are crushed to about 8 inches if destined for use in an open-hearth furnace and a maximum of 4 inches if destined for use in a blast furnace. Within the last few years it has become common practice to remove minus ¼-inch material from all ore sold on the open market. The coarse material then is graded and sized to customer's specifications. Minus ¼-inch material is sold at a discount or agglomerated by one of several processes described later.

Soft, iron-bearing material containing clay and sand in which the iron is concentrated in a coarser and harder portion is beneficiated by washing. The ore is crushed, screened, and then washed in log washers or on screens and in various types of classifiers. In some plants, bowl classifiers are used for separating fine iron minerals from the log washer tailings. From 45 to

70 percent of the iron is recovered in a product ranging from 40 to 60 percent iron. Reject fines from washing plants contain from 10 to 45 percent iron (in extreme instances).

Gravity concentration by jigging or heavy-medium separation equipment is applied to concentrating coarse ore (usually plus ¼-inch and seldom finer than ⅛-inch), and Humphrey spirals, and wet cyclone separators (both with and without suspension medium), are used for concentrating fine ore and the tails from jigs and heavy medium wash plants. Each type of gravity concentration equipment has certain advantages or disadvantages, depending on the physical characteristics of the ore and on the difference in the specific gravity of ore and waste. Heavy medium cyclone separators have high capacity and make a good separation. Humphrey spirals make a better separation of fine material than cyclones, but do not have as high capacity. Heavy-medium units make a sharper, more rapid separation on unsized coarse ore than do jigs. Among the various types of gravity-separation equipment, cyclones (heavy medium) and other types of heavy-medium plants seem to be most favored by the large producers.

Magnetic concentration would present the answer to iron-ore beneficiation if the ores contained only magnetite. Unfortunately, in the preponderance of so-called magnetite iron ore, including the taconites, the iron is distributed in magnetic and nonmagnetic iron minerals and in iron-bearing silicates. Consequently, the overall recovery of a typical magnetic concentration plant ranges from 30 to 95 percent of the iron in the feed. In many instances the tailings contain silicate minerals from which a desirable iron-bearing product cannot be recovered by present methods, but they also contain recoverable iron in the form of oxide minerals.

Essentially all types of magnetic separators have been applied to concentrating magnetite ore, but most operators have settled on the belt units for cobbing and rougher concentration and on drum units for finishing. If the ore is ground finely enough to liberate the mineral constituents, magnetic process plants recover 95 percent or more of the magnetic iron content of the ores in a 62 to 68 percent iron concentrate. The siliceous magnetite iron-bearing formations of the Lake Superior district require grinding to pass 100-mesh (75 to 92 percent minus 325-mesh); not even a 500-mesh grind, however, will liberate iron minerals from materials obtained from some parts of the district's slaty formation material.

The distribution of iron by mineral in the nonmagnetic cherty taconite on the Mesabi range between Grand Rapids and Buhl, Minn., as determined by the Bureau of Mines, is as follows:

Mineral	*Percent of total iron content*	*Range (percent)*
Magnetite	21. 3	0–66
Nonmagnetic oxides	[1] 74. 8	5–100
Siderite	2. 7	0–90
Silicate	1. 2	0–90

[1] By difference.

Magnetic taconites currently mined contain 60 to 70 percent of their total iron in magnetite minerals and the remainder in nonmagnetic oxide and silicate minerals.

Nonmagnetic iron minerals can be concentrated with conventional magnetic separators by converting them to magnetite in a controlled reduction roasting atmosphere in shaft, multiple hearth, or rotating cylindrical furnaces.

Iron ore concentration with high-tension separation equipment that imparts differential movement of mineral particles with a grounded rotor and a concentration of mobile ions was reported in 1957 (*18*). Reportedly the equipment compared favorably with commercial magnetic and flotation separation equipment in semi-pilot plant tests on hematite, magnetite, and martite ores, but it has not yet been applied on a large scale commercially. Nevertheless, electrostatic separators continue to be of interest to researchers seeking profitable methods of concentrating complex iron ores.

The Mines Experimentation Station of the University of Minnesota is conducting a pilot-plant study of a process for beneficiating low-grade Mesabi range ores in which electrostatic and high-intensity wet magnetic separation circuits are used to concentrate part of the iron minerals.

Specular-hematite ores are concentrated efficiently with flotation, and flotation is applied to concentrating the fine-grained hematite minerals in material from which part of the iron minerals have been removed by other methods.

Flotation also has been applied successfully for upgrading iron ore concentrate by floating silica, apatite, and other mineral impurities away from the iron minerals. The art and science of applying flotation to concentrating iron ores has been advanced markedly in the last decade, but reagents and procedures have not been found that are commercially applicable to ores containing mixtures of limonite, goethite, and hematite.

Agglomeration (2, 5, 21, 27)

Fine-grained iron ore and iron ore concentrate is agglomerated before being smelted in a blast furnace by sintering, nodulizing, pelletizing, or briquetting. The fine ore is sintered with heat on traveling grates or in a batch ma-

chine, nodulized with heat in a rotary kiln, pelletized without heat in a rotating drum, pan, saucer, or cone, or briquetted without heat using some form of binder in pressure-roll machines. Hot ore briquetting processes have been successful on a laboratory scale using pressure rolls to form the briquettes, but a 2-year pilot-plant test on Lake Superior fine grained siliceous ore indicated that the operation would not be profitable because of high maintenance costs. Together the several types of materials produced is called agglomerate; individually they are called iron-ore sinter, nodules, pellets, and briquettes. Pellets and usually briquettes are indurated by some form of heat treatment after they are formed. The pellets are treated in updraft or downdraft traveling grate furnaces, in shaft furnaces, or in grate-kiln furnaces. Each method has its advantage. Data are not available to determine which is the better under all circumstances.

Self-fluxing agglomerates, wherein fuels, flux, and iron minerals are combined, present theoretical possibilities for saving in the cost of operating a blast furnace. The principal advantage is that the flux would be calcined before it reached the furnace. Lime sinter, which contains less than enough basic material to neutralize all the acidic materials in the ore, is in common use, but completely self-fluxing agglomerates are still not widely used.

Bureau researchers have produced partially reduced pellets in the laboratory and on a pilot plant scale. Partially reduced pellets are those in which most of the oxygen has been removed from the contained iron oxide minerals. These pellets were proved superior blast furnace feed in the Bureau's experimental furnace, and similar pellets have been tested in commercial furnaces, but the results have not yet been published.

Smelting (1, 22, 24)

Blast furnaces are used to smelt more than 93 percent of the iron ore consumed in the United States, open-hearth furnaces are used to smelt about 6 percent, and electric furnaces producing ferroalloys are used to smelt less than 0.2 percent. Their proportions have been about the same since the turn of the century despite concerted efforts by many researchers to develop alternatives for the blast furnace. The fact is that the blast furnace is the most efficient tool for smelting iron ore yet developed. Its use over more than three centuries has progressed from crude art to highly sophisticated metallurgical technology. Probably more has been done to increase its efficiency in the last 10 years than was done in the preceding 100.

The average blast furnace in the United States is 95 feet high and 23 feet in diameter at the hearth, it has a working volume of 33,200 cubic feet, and will produce about 1,200 tons of pig iron (hot metal) per day. The largest furnace in the United States is the Armco Steel Corporations' "Amanda" at Ashland, Ky. The "Amanda" is 104 feet high, 30 feet 6 inches in diameter at the hearth, has a working volume of 68,510 cubic feet, and capacity to produce 3,340 tons per day. Record monthly production, however, was held in 1964 by the Bethlehem Steel Co.'s "J" furnace at Sparrows Point, Md., with 104,435 tons of iron produced in October 1963. The "J" furnace is 105 feet 3 inches high and has a hearth diameter of 28 feet 9 inches and working volume of 50,522 cubic feet.

Nor is the Amanda the world's largest blast furnace. This distinction is claimed by Tokai Iron & Steel Co. Ltd.'s No. 1 blast furnace at Nagoya Harbor, Japan, which has a hearth diameter of 32 feet 2 inches, working volume of 71,371 cubic feet, and daily capacity of over 3,500 tons.

The smallest iron blast furnace in the United States has a height of 55 feet, hearth diameter of 7 feet, working volume of 3,316 cubic feet, and capacity of about 100 tons per day. It has been used principally to produce ferroalloys but was not operating in 1964.

Small blast furnaces have proved uneconomic principally because of the cost of labor. It takes about the same crew to operate a small furnace as it does a large one. Therefore, there has been an unbroken trend since World War II to build larger furnaces. Apparently the structural limit has not yet been reached as Russian metallurgists have announced plans to build a furnace with a 36-foot hearth diameter and 95,000 cubic feet of working volume.

The chemistry of the blast furnace is extremely complex. At least 27 chemical reactions are possible, but simply stated the furnace performs two functions: (1) it reduces iron oxide to metal, and (2) it fuses the charge so that metal and slag will separate. Coke is the principal fuel and reductant, and limestone and/or dolomite is used for flux. These materials are charged with the ore into the top of the furnace. Coke is the most expensive material, and the largest single cost item in iron ore smelting. Within the last decade, methods have been devised to save coke by injecting part of the fuel and reductant needed into the smelting zone of the furnace. Various gases, oils, and powdered coals have been used successfully for this purpose. Availability and cost determine the choice. Natural gas has been the principal alternative fuel used in the United States. Fuel oil has been the principal alternative in European countries. Theoretically, more coke can be saved using powdered coal, but reliable tech-

niques for injecting the coal were not developed until 1962. Coal injection was reported to the Bureau for the first time in 1963 when 29,303 tons of bituminous coal and some anthracite, 43.9 million gallons of oil, 3.8 billion cubic feet of coke oven gas, and 31.6 billion cubic feet of natural gas were used in blast furnaces.

Blast furnace efficiency is judged by the ratio of fuel consumed to the iron produced. Recovery of the iron in the feed is over 93 percent. Capacity or productivity is related to efficiency and varies widely depending on the quality and characteristics of the charge in addition to depending on the operation of the furnace. Furnace capacities were published until 1960, but the practice was discontinued because the figures were widely misunderstood and misinterpreted. Furthermore, advancing technology made the capacity figures all but meaningless in terms of the metal that could be produced in a given size furnace.

Blast furnace operations have been greatly improved in the last two decades: (1) by grading and sizing the burden (charge without fuel); (2) by increasing the temperature and oxygen content of the blast; (3) by the fuel injection discussed above; (4) by increasing the rate and pressure of the blast; and (5) by using a burden that contains more iron per unit volume. Iron ore pellets have been accepted in the United States as the best material to obtain optimum furnace operation. However, in Europe, sized and graded sinter prepared from high-grade ore is considered superior to pellet by some furnace operators. Relative reducibility, tempered by length of experience with each, probably is responsible for the choice. Use of either high-grade pellet or sinter leads to better furnace operations and their physical and chemical characteristics set the standards by which other iron raw materials are measured.

Theoretically, use of partially reduced pellets will improve blast furnace operation and increase capacity as much as have pellets and sinter. Furthermore, the advantage of using them has been demonstrated practically in the Bureau experimental blast furnace, so there is little doubt that they will be used commercially if their cost is not prohibitive. Preliminary estimates indicate that the cost of iron in partially reduced pellets delivered to most blast furnaces will be little more than the cost of iron delivered in pellets; therefore, partially reduced pellets probably will replace pellets for feed to furnaces in which there is need to increase output. That is, additional iron ore smelting capacity will be obtained by using prereduced pellets, rather than by building new blast furnaces.

Electric-furnace smelting has proved marginally competitive with the blast furnace in areas of inexpensive electricity a long distance from a supply of coke. Almost any carbonaceous material will serve for the reductant in an electric furnace. The Bureau has had marked success with wood chips. Flux requirements are essentially the same as for a blast furnace.

Sponge-iron processes, in which the ore is reduced at temperatures below the fusion point of iron, and direct iron processes, in which the ore is reduced at a temperature slightly higher than the fusion point, present possible alternative methods of producing iron. Scarcity of coke, or in some areas impending depletion of coking coal and high relative prices of coke in others, and changing economic and technologic conditions, often make these processes exceptionally attractive. Periodically since 1910, research institutions and industrial organizations have shown great interest and activity in developing processes to replace blast furnace smelting. A great deal of research effort has been expended on direct reduction possibilities. Several hundred processes have been developed through successful laboratory tests, and a dozen or more have been successfully tested in semicommercial pilot plants. At least five and possibly more are being applied commercially in specific physical and economic environments (*11*, *12*, *23*, *28*).

It is at times impossible to distinguish between semicommercial pilot and commercial operations. Höganäs and Wiberg-Soderfors, true sponge iron processes developed in Sweden, have long records of successful continuous commercial applications in that country. The Krupp-Renn, and "H-Iron" processes, have been applied commercially but in some instances have been found inapplicable with changing economic environments. Since its inception the Hy-L process has been used successfully and continuously to make sponge iron at Monterey, Mexico, and the Echeverria process has been used the same way at Legazpia, Spain. The R–N, S–L, and Strategic-Udy processes have been tested successfully in semicommercial plants and are offered as processes commercially applicable to processing selected iron ores under some conditions. In addition, several fluidized bed processes for obtaining iron from high-grade concentrate have been tested on a large scale. These processes also are offered as commercially applicable under some conditions.

Table 2 presents an elementary comparison of selected direct-reduction processes. The reader is referred to the work of Barrett, of the Bureau of Mines (*4*); Brown, of Jones and Laughlin Steel Corp.; (*7*) and Chase and McBride, of the United States Steel Corp. (*10*) for comprehensive discussion and review of the principal sponge iron and direct iron processes.

TABLE 2.—*Comparison of principal iron ore direct reduction processes*

Item compared	Krupp-Renn	R-N	Strategic-Udy	H-Iron	Hy-L	Echeverria	S-L
Possible ore feed	Low-grade high silica but low in sulfur and phosphorus.	Any-grade lump sulfur and phosphorus not critical.	Any-grade—but ¼ inch or finer Low in sulfur and phosphorus.	High-grade fine	High-grade lump	High-grade lump, sinter, or pellet.	High-grade lump ore or pellets.
Flux	None	Limestone—for sulfur only.	Limestone	None	None	Limestone—for sulfur only.	Dolomite for sulfur only.
Reductant	Solid carbonaceous, fairly low-grade.	Solid carbonaceous, excess recycled.	Solid carbonaceous	Hydrogen	H_2-CO-gas	Solid carbonaceous, excess recycled.	Coal.
Reducing temperature.	1,250° C	982° to 1,093° C	1,100° to 1,300° C	480° C to 538° C	About 1,100° C	1,050° C	1,090° C.
Pressure	Atmosphere	Atmosphere	Atmosphere	400 psig	Atmosphere	Atmosphere	Atmosphere.
Source of heat	Solid carbonaceous, fairly low-grade, or fuel oil.	Oil, gas, or solid burner fuel.	Gas from electric furnace in circuit plus other gas.	Any	Natural gas	Fuel oil, natural gas, producer gas, etc.	Gas.
Equipment	Rotary kiln	Rotary kiln	Rotary kiln Short-arc electric furnace.	Fluidized-bed pressure vessels, at least three.	Four retorts Heat accumulator.	Vertical retort, external heat.	Rotary kiln.
First product	Mixture of slag and luppen.	Mixture of fuel-slag and iron.	Partially reduced ore-flux mixture.	Iron powder with slight impurities.	Sponge, 85 percent iron	Mixture of fuel slag and iron.	Mixture of fuel slag and iron.
Second treatment	Magnetic separation	Gravity separation for fuel then ground, wet, magnetic separation.	Short-arc electric furnace.	Compression mechanism.	None	Screening and magnetic separation.	Screening and dry magnetic separation.
Second product	Iron (luppen)	Iron briquets over 95 percent iron.	Pig iron or semi-steel	Iron chips or powder	None	Sized sponge iron	Sponge iron pellets and briquets.
Apparent advantages.	Low-grade ore Low-cost fuel Iron recovered from silicates.	Flexibility Low-grade ore Low-cost fuel Removes sulfur and phosphorus.	Low-grade ore Produces semi-steel Sulfur and phosphorus can be removed selectively Flexibility.	No trouble with fine concentrate Wide degree of reduction possible Product will replace all or any part scrap and ore charge to steel furnace.	Replaces scrap Most sulfur eliminated.	Replaces scrap Simplicity—small units are efficient Most sulfur eliminated.	Removes sulfur and phosphorus.
Apparent disadvantages and operating problems.	Sulfur and phosphorus remain with iron.	Low recovery in silicate iron mineral ore.	Must have inexpensive source of electricity.	Must have high-grade fine ore Does not remove any contaminants.	Requires high-grade ore and low-cost gas and power.	Must have high-grade ore Does not remove phosphorus.	Process not developed to process low-grade or siliceous ore.
	Ring formation in kiln	None	Ring formation in kiln	No choice of reductants.	Does not remove phosphorus Batch system.	Batch system	None.

The Krupp-Renn process probably should be classified as a beneficiating process rather than a sponge iron process because it has been used almost exclusively to upgrade siliceous ores. It is a rotary kiln process to which fuel ore mixtures are fed to a internally heated kiln. The iron oxides are reduced to metal and the iron gathers in nodules or lumps at the lower end of the kiln. The product is cooled and fed to a ballmill and then to a magnetic separator. The lumps, called "luppen" contain 90 to 95 percent iron. Availability of high-grade ores has made the Krupp-Renn process obsolete in most parts of the world. Krupp-Renn plants are still being operated in Czechoslovakia, but those in West Germany where the process was developed have been shut down or are operating on high-grade ore.

The R-N process is a refinement of the Krupp-Renn process. It also is an internally heated rotary kiln process, but the temperature is carefully controlled so that at no point in the kiln does it exceed the fusion point of iron. The grade and grain-size of ore fed to an R-N kiln are not significant except that retention time becomes excessive if the ore lumps exceed 1½ inches in diameter, or the reduction time is excessive at smaller diameters if the ore is very dense. Limestone or dolomite is added in small quantities to arrest sulfur. The kiln can be fired with either an oil, gas, or solid-fuel burner, and the temperature gradient throughout the kiln is closely controlled by limiting the quantity of air available for combustion. Kiln products are separated by screening, gravity, or magnetic processes; and the unused solid-carbon reductant is cleaned and returned to the circuit. The iron-bearing portion is pulverized and separated magnetically and the iron is pressed into metallic briquets of high strength and density.

The S-L process is essentially the same as the R-N process except that it has been applied only to high-grade lump ore and pellets.

Recognizing this similarity the proprietors of the R-N and S-L processes have agreed to license their joint technology to Lurgi Gesellschaft fur Chimie und Huttenwesen m.b.h. of Frankfurt (Main), West Germany, for an improved direct reduction process, known as the SL/RN process.

The Strategic-Udy process can utilize any grade iron ore, but the particle grain size should be one-fourth inch or less because the economy of the process is dependent on rapid throughput. The ore is partially reduced in a rotary kiln at 1,100° to 1,300° C, and fed directly from the kiln into a short-arc electric furnace. Solid carbonaceous material and gas from the electric furnace partially reduce the ore in the kiln. The solid carbon not used in the kiln is "coked" and passes through to finish reducing the ore in the electric furnace. Limestone or dolomite flux as needed is fed to the kiln with the iron ore.

The Hy-L and Echeverria processes are true sponge iron reductions in that the temperature is never permitted to exceed the melting point of iron and in that the end product is used as is in steelmaking. Both processes require high-grade iron ore or concentrate because all impurities are carried through to the iron end product.

In the Hy-L process, the ore is reduced in four identical reduction reactors each with a capacity of approximately 100 tons of raw ore. The system operates on a 12-hour cycle during which the reactors pass through four stages of 3 hours each. In the first stage, the ore is preheated with hot gas and the reduction process is started. Most of the ore is reduced in the second stage. The remainder is reduced and the charge takes on approximately 2 percent of combined carbon in the third stage. In the fourth stage, the ore, now sponge iron, is cooled and the heat is recuperated and used to preheat the ore in the first stage. The final product is a sponge iron averaging about 85 percent metal from which 85 percent of the sulfur has been removed. The sponge is suitable for use wherever cold iron melting stock is normally employed.

Although the chemistry and metallurgy of the Hy-L and Echeverria processes are similar the mechanics are completely different. Ore in the Echeverria process is charged with any low volatile carbonaceous fuel into externally heated shaft-retorts. A small amount of limestone is mixed to the ore to pick up the sulfur. Retorts are about 10 meters high with a circular horizontal section slightly tapered to permit free descent in the column. The retorts are installed within a refractory-lined oven which is heated by combustion of producer gas. Time from charge to discharge is approximately 48 hours depending on the reducibility of the ore. Each retort has a capacity of approximately 1.4 tons of iron product per day. The product is screened into three sizes and then separated from the excess coal and limestone magnetically. The screened sponge products are used in any cold melting stock operation similar to the Hy-L sponge.

The H-Iron process is a fluidized-bed reduction and therefore requires high-grade, fine-grained iron ore or concentrate. As in the Hy-L and Echeverria processes, most impurities are carried through the process to the end product. The ore is reduced with hydrogen at 480° to 538° C, under 400 pounds per square inch, gage pressure (*31*). The product is an impure iron powder that can be compressed to

form chips suitable for a steel-furnace charge, or the powder can be fed directly into an electric furnace by a method developed cooperatively in Bureau laboratories (*3*).

Electric-furnace smelting of iron ore, and the various sponge-iron and direct-iron processes are not used in most instances in this country because they cannot compete in production costs with the blast furnace, but they have the following advantages that make them attractive in some geographic areas: (1) they would not require as large a capital investment as a blast furnace; (2) impurities, such as sulfur in coke, would not be introduced in the same extent; (3) they apparently can recover iron from complex minerals with a byproduct slag enriched in other metals; and (4) they can afford better product purity control.

USES

Iron ore, in addition to supplying the metal for iron and steel products, is used in paint pigments, cement, basic refractories, as a fluxing agent in nonferrous smelting and as a constituent of some catalytic agents. Lump magnetite ore is used for heavy aggregate in concrete for covering underwater pipelines, as a shielding material in nuclear powerplants, for the medium in jig beds and sink floatplants, and during World War II it was used for ship ballast.

BYPRODUCTS AND COPRODUCT RELATIONSHIPS

Iron is obtained as a coproduct in the mining of copper, lead, zinc, and nickel in operations whereby iron sulphides are separated from other metal minerals and then roasted to drive off the sulfur, leaving a residue of high-grade iron oxides. The residue, called iron cinder, is sintered to make an iron product which commands a premium price.

Iron is also obtained from the magnetite produced with the mining of titanium minerals, and as a byproduct when titaniferous ores are smelted to recover TiO_2. Magnetic iron minerals are separated in an iron concentrate, and if the concentrate contains too much titanium, it may be blended with other iron-bearing material to form suitable blast-furnace feed.

Many heavy mineral placer concentrates contain some magnetite. If the operation is large enough, and the mine location is favorable, the magnetite is separated and marketed.

Titanium-bearing iron ores are not utilized for blast-furnace feed in the United States at present because under normal furnace operation titanium forms oxide accretions in the bottom of the furnace. Few domestic mineral deposits contain enough titanium to be mined at present for that element alone.

SECONDARY SOURCES AND RECOVERY

Secondary iron is recovered from flue dust, mill scale, and from scrap iron and steel that is unsuitable for steel furnaces. Iron and steel scrap comprises about 50 percent of steel furnace feed and is a raw material often considered vital to the operation of ferroalloy furnaces.

The scrap supply follows the demand, but data have not been developed to predict accurately the supply that will be available under specific circumstances.

Unrecoverable losses of iron from the mine or beneficiation plant through its cycle of use range as follows: Loss in shipments from the mines to the steel mills is believed to be small. Blast-furnace loss ranges from 1 to 1.5 percent in plants that have dust collectors and Cottrell precipitators. Without this equipment, the loss is about 7 percent. Iron loss in ferroalloy and steel furnaces ranges from 2 to 3 percent. In addition to these furnace losses, there is also a loss of about 1 percent, which cannot be accounted for between the feed to the blast furnace and steel mill shipments. Estimates of irretrievable fabricated steel losses range from 12 to 25 percent or more. Thus, total unrecovable iron losses through a complete cycle from mine to use and secondary recovery range from 16 to 36 percent.

RESOURCES

The total resources of iron ore available to industry have increased sharply in recent years, in particular because improved beneficiation can now produce high-grade materials economically from the very abundant low-grade metamorphosed sedimentary iron formations. Formerly only those parts of the iron formations that had been concentrated by natural geologic processes could be used. However, availability of high-grade, physically desirable blast-furnace feed has reduced the demand for certain natural ores, causing substantial shifts in the sources of iron ore.

Resources are unquestionably sufficient for centuries; they are reasonably well distributed around the world, and the major factors to be weighed in selecting particular areas to develop are those of costs (mining, beneficiation, transportation, and taxation), political stability, and security. Nevertheless, very real differences exist in the geologic settings (continuity, thickness, attitude, etc.), which affect mining costs, and in the mineralogy of the ores, which determine the feasibility of economical ungrading.

The resource figures in the following tables were compiled by the Geological Survey from many sources. They are approximations of quantities and grades known to exist in selected areas of the world that are either in exploitation now or for which there is reason to believe that development may take place in the relatively near future. No attempt is made to break them into the traditional measured, indicated, and inferred categories. Most of the material, even of the highest grade, will undergo some form of beneficiation before use; the grade figures give a general idea of the concentration ratio between ore in the ground and the quantity of "usable iron ore" that can be produced.

TABLE 3.—*Iron ore resources of the United States* [1]

[Million long tons]

Region	Quantity	Percent iron	Type
Northeast (New York, New Jersey, Pennsylvania).	300	30–50+	Magnetite.
	1,000	25+	Magnetite, hematite.
Southeast (Alabama, Georgia, Tennessee).	8,000	30–38	Red (hematite) ore.
	50	38–57	Brown (limonite) ore.
Lake Superior (Minnesota, Michigan, Wisconsin).	500	50–54	Direct shipping.
	>100,000	22–30+	Taconite, jaspilite.
South Central (Missouri, Texas).	250	40–60	Magnetite, hematite.
	150	40+	Limonite and siderite.
Rocky Mountain (South Dakota, Wyoming, Colorado, New Mexico, Utah).	500	48–60	Hematite and magnetite.
	2,000	25–40	Taconite.
Northwest (Montana, Idaho, Washington, Oregon).	15	40–60	Limonite, magnetite, hematite.
	1,000	25–40	Taconite.
Southwest (Arizona, California, Nevada).	100	50+	Magnetite.
	2,000	25–40	Magnetite and taconite.

CONSERVATION

If it must be removed from the pit, low-grade iron ore is saved at most open-pit mines by stockpiling it in spoil banks so that it can be recovered when changing technologic or economic conditions make such recovery profitable. A few concentrating plant operators have constructed their tailing ponds so that the tailings can be retreated. Substandard iron ore is mixed with high-grade ore to produce a greater tonnage of usable product if buyer's specifications allow it.

SOURCES OF STATISTICAL INFORMATION

The Bureau of Mines canvasses major iron-ore producers monthly, and all producers annually. These canvasses are conducted in close cooperation with State agencies and industry trade associations. Export and import data are compiled by the Bureau of Mines from records of the Bureau of the Census, Department of Commerce. The Bureau of Mines also compiles iron-ore production statistics for foreign countries from official foreign government publications and from consular reports of the Department of State.

Bureau coverage of the domestic industry is practically 100 percent; mine production figures for small mining operations that fail to report are obtained from consumer's purchase records. Coverage of foreign iron-ore statistics is complete except for the U.S.S.R. and its satellites, and the figures are as accurate as the limited number of mineral attaches in foreign countries permits. The Bureau publishes iron-ore statistics monthly in Mineral Industry Surveys and annually in the Minerals Yearbook.

The American Iron Ore Association publishes monthly Lake Superior iron-ore shipments from United States and Canadian ports, monthly stocks of iron ore and agglomerates at U.S. docks and furnace yards, U.S. and Canadian monthly consumption of iron ore and agglomerates by districts and processes, and an annual statistical report of shipments of Lake Superior iron ore to upper Lake ports and all-rail shipments to consumers. U.S. production of pig iron and steel, with corollary statistics, are published weekly, monthly, and annually by the American Iron and Steel Institute. Together, these statistical data present completely adequate coverage of the iron ore industry through the blast furnace, but beyond the blast furnace many pertinent data on iron production, consumption, and stocks are lacking.

PRODUCTION, CONSUMPTION, AND TRADE

The relative position of the iron producing districts and the changes in quality and the extent of concentration practiced in each are shown in table 5.

The Lake Superior district has been the principal source of domestic iron ore. Its production of crude ore has remained about the same for the last 10 years, while its production of usable ore has declined steadily. The grade of usable ore produced, however, has increased steadily.

TABLE 5.—*Crude and usable iron ore produced in the United States, grade of usable ore, and ratio of concentration, by districts*

Year	Crude ore mined (thousand long tons)	Usable ore produced		Ratio of crude ore to usable ore
		Quantity (thousand long tons)	Grade (percent)	
	Lake Superior district			
1949	79,306	68,494	50.77	1.2:1
1950	96,561	79,627	49.75	1.2:1
1951	115,846	93,947	51.10	1.2:1
1952	94,933	77,095	50.35	1.2:1
1953	120,425	95,655	50.46	1.3:1
1954	80,725	60,994	50.99	1.3:1
1955	109,118	83,255	51.28	1.3:1

[1] Includes 39,219 tons of ore from Puerto Rico in 1951; 138,613 tons in 1952.

The Southeastern district was the second ranked source of domestic iron ore until 1957, but since then its production of crude and usable ore have declined, and in 1963 it produced less than any of the other recognized districts. The tenor of usable ore produced there has remained about the same, but the grade of crude ore mined has declined.

The Northeastern district has maintained its position among the iron ore districts, producing about the same quantity of crude and usable ore. The average grade of usable ore produced in the district has increased slightly in the last decade.

The Western district also has maintained its position while producing an increasingly better grade of usable ore.

The United States uses from 120 to 125 million tons or more of iron ore per year, or roughly 1,300 pounds of iron in ore for each ton of steel produced. Most of it is smelted to produce iron, but small quantities are used in making cement, special high-density concrete, and paint pigments, and magnetite concentrate is used for heavy-medium in coal processing plants.

Iron ore has become a significant part of the foreign trade of the United States as domestic production has fallen steadily, and imports have increased to supplant domestic mines in supplying the country's needs, figure 1.

The chart, figure 2, showing the average grade of imports and the average grade of iron ore produced in the United States in the last two decades provides insight into this competition for the domestic market. It is apparent that the average grade of usable ore produced in the United States ultimately will equal or exceed that of imported ore.

Most of the U.S. foreign trade in iron ore has been with Canada. Venezuela supplanted Canada as the principal supplier for a short time, but considering both exports and imports, iron ore trade with Canada has always been the larger.

From 1960 to 1963 Canada supplied 44 percent of iron ore imports; Venezuela supplied 35 percent; Chile 10 percent; and Peru about 4 percent. Most imported blast furnace ore originates in these four countries. Most of the open-hearth, lump ore originated in Brazil and Liberia, with lesser amounts from Venezuela and Chile.

The United States sells about 5 million tons of iron ore per year to Canada and more than 1 million tons to Japan. Sales to Canada are essentially trades made to cut down the transportation costs in each country.

Iron ore is not subject to tariffs.

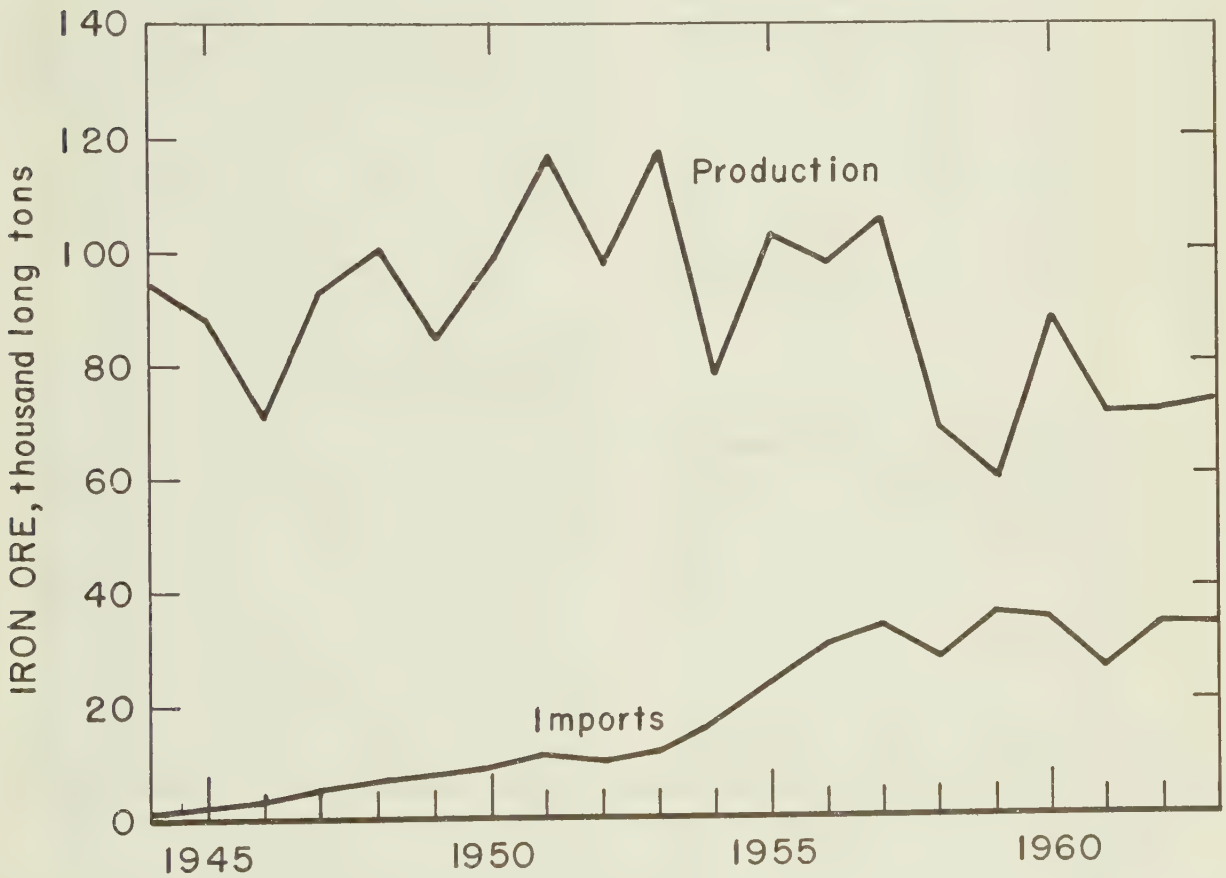

FIGURE 1.—United States Iron Ore Production and Imports for Consumption.

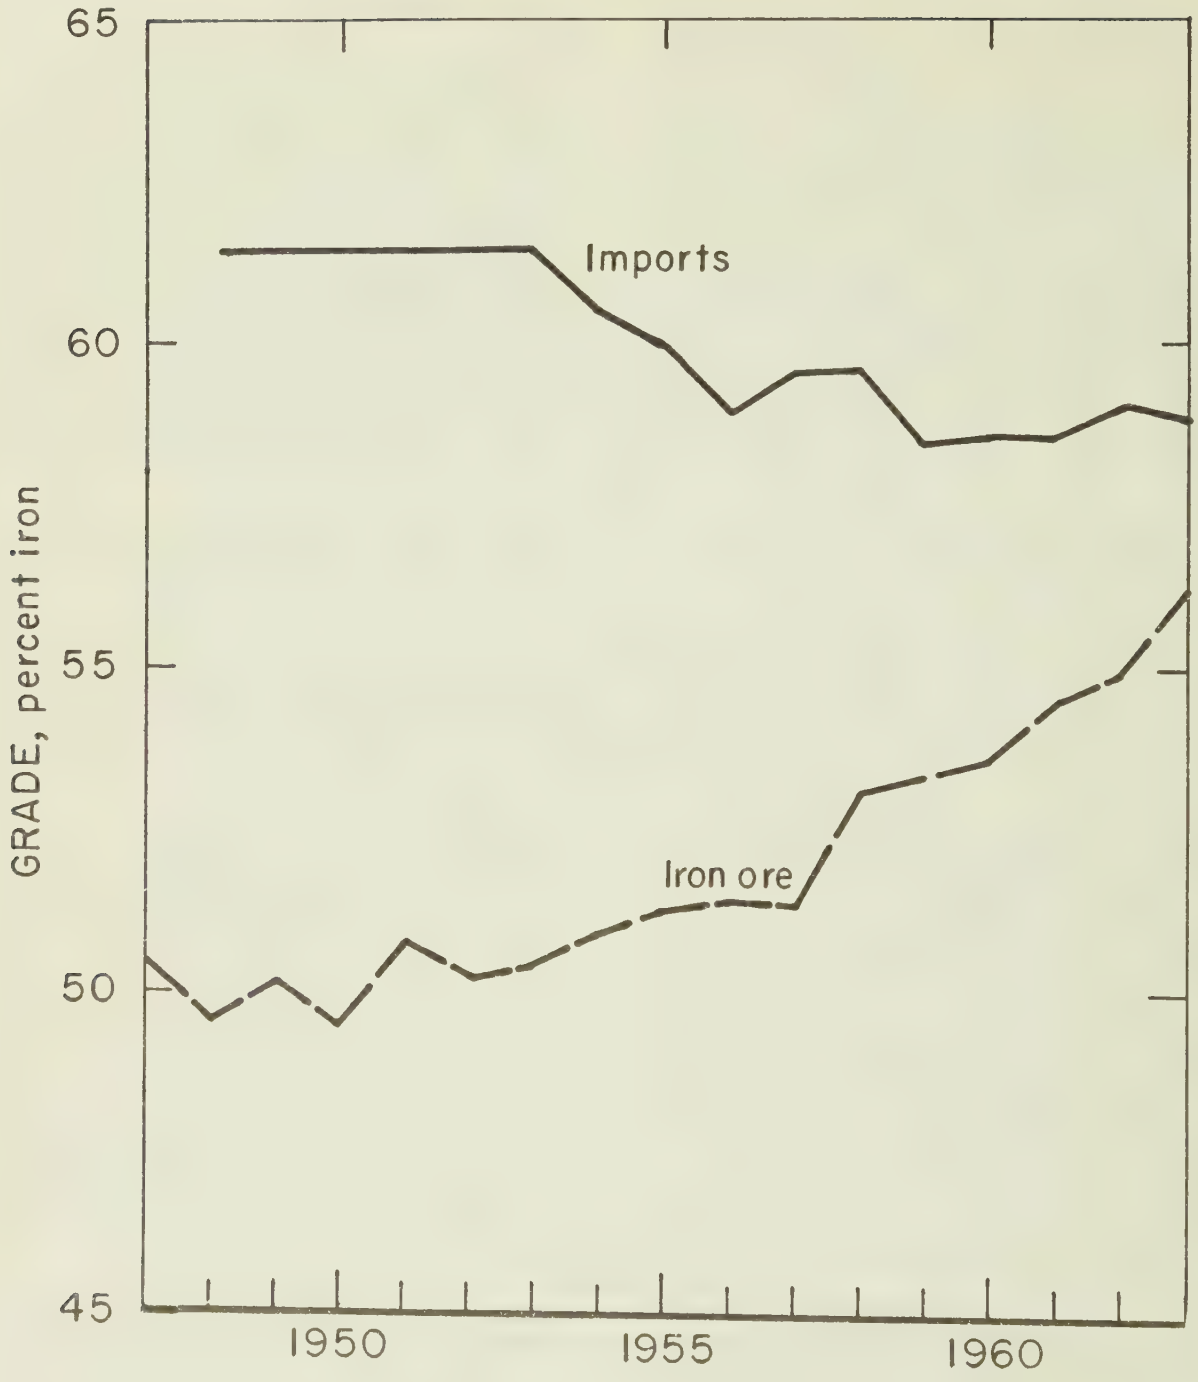

FIGURE 2.—Average Grades of Domestic and Imported Usable Iron Ore Consumed in the United States.

STRATEGIC CONSIDERATIONS

Iron is absolutely essential to the economic well-being and safety of the United States. The principal danger to supply is vulnerability of the transportation system. Most of the Lake Superior district iron ore moves to markets through the Great Lakes, and this movement is essential if the country is to have an adequate supply of iron ore because railroads do not have enough capacity to replace the Lake transportation system. Furthermore, the St. Lawrence Seaway carries 10 to 15 million tons of iron ore annually from Canada to the steel-producing centers on the lower Great Lakes, and the United States is partially dependent on iron ore from South America. Stockpiling iron ore, to date, has been deemed impractical.

The United States emerged from the era of peacetime self-sufficiency in high-grade iron ore about the latter part of the 1940's. In an emergency, however, the United States could be self-sufficient for 2 or 3 years. This does not mean that there is not enough iron ore in the country to supply our needs, only that its geographic distribution is such that the output cannot be easily increased. If ore from Canada were available, the two countries probably could be self-sufficient indefinitely.

GOVERNMENT PROGRAMS

The Defense Production Act of 1950 included provision for government assistance in exploration and development of iron-ore deposits, and the Internal Revenue Act of the same year provided accelerated tax amortization for new and expanded iron-ore production facilities. Iron-ore exploration assistance was continued until May 15, 1953, when it was suspended. It was reactivated again by order of the Secretary of the Interior on July 24, 1961, and is still available January 1965. Rapid tax amortization incentives were continued through September 29, 1955. During the time the expansion goal permitting rapid tax amortization of capital invested in iron-ore facilities was in effect, planned investments under the program totaled over $1.25 billion.

PRICES AND COSTS

Table 6 gives the Lake Erie price for iron ore, 1955–59 average and 1960–64. Lake Erie base prices are established each year by publication of a major contract between a prominent iron ore producer and a steel corporation. Other companies follow this lead and negotiate contracts accordingly. Lake Erie base prices are published each year before the start of the Lake Superior shipping season by several trade journals and by leading mining companies.

Current iron-ore mining costs range from about $2.50 per ton in open pits to $10 or more per ton in underground mines. The average production costs of iron ore produced in underground and open pit mines in Minnesota, 1952–56 average and 1957 to 1961, are given in table 7.

TABLE 6.—*Lake Erie base prices of iron ore, per long ton, 51.5 percent iron, natural*

Year	Old range bessemer	Old range nonbessemer	Mesabi bessemer	Mesabi nonbessemer
1955–59 (average)	$11.44	$11.29	$11.21	$11.06
1960	11.85	11.70	11.60	11.45
1961	11.85	11.70	11.60	11.45
1962	11.05	10.90	10.80	10.65
1963	11.05	10.90	10.80	10.65

TABLE 7.—*Average cost per long ton of mining and beneficiating iron ore in Minnesota* [1]

Year	Development	Labor and supplies	Other [2]	Royalty	Total
1952–56 (average)	$0.625	$0.905	$0.915	$0.433	$2.878
1957	.660	.989	1.145	.474	3.268

[2] Includes beneficiation.

TAXES

Federal tax laws allow iron-ore miners a 15 percent depletion deduction from gross income to arrive at net taxable income. Direct State taxes are levied on reserves, both developed and undeveloped. In some instances, however, reserve tax laws for low-grade deposits have been relaxed, and now only low-grade ore production is taxed.

EMPLOYMENT AND PRODUCTIVITY

The number of men employed at domestic iron mines and beneficiating plants has declined about one-third since World War II. Employment has been related to usable ore production but has not fluctuated with it directly because mining companies have planned operations to maintain a stable labor force. The mining companies have also kept most men employed year round. These practices have obscured productivity measurements so that year to year comparisons are not signficant. For example, data reported to the Bureau indicates that output per man in 1955 was 1.78 tons of usable ore per hour, and in 1962 it was 1.72 tons per hour.

There is no doubt, however, that the trend in productivity is upward. Output was only 0.75 ton per man-hour in 1923, the first year employment figures were reported to the Bureau.

TABLE 8.—*Employment and productivity at iron ore mines and beneficiating plants*

Year	Average number men employed	Productivity, tons usable ore per man-hour
1925	35,757	.717
1930	30,975	.816
1935	14,987	1.162
1940	25,128	1.512
1945	26,777	1.465
1950	31,087	1.492
1955	29,000	1.78
1960	27,543	1.63
1962	21,010	1.72

TRANSPORTATION

More than 75 percent of the iron ore produced in the United States is transported in ore carriers on the Great Lakes. The Great Lakes' fleet in 1964 numbered 170 vessels. Their average age was 41 years. The quantity of ore that the fleet can move in any one year varies according to the length of the shipping season; the annual carrying capacity under the most favorable circumstances is 76.3 million long tons.

Iron ore transported over the Great Lakes system is transferred a minimum of 3 times (rail, to loading dock, to ship, to railroad) and a maximum of 5 times (mine truck, to railroad, to loading dock, to ship, to stockpile, to railroad). Each transfer generates additional fines that detract from the value of the ore. Blending of ore from various mines to assure a guaranteed analysis is an integral part of the mine-to-rail-to-ship transportation system.

The St. Lawrence Seaway carries over 12 million long tons of foreign iron ore annually to Great Lakes ports of the United States. This ore comes principally from the Quebec-Labrador iron belt of Canada via rail to river ports and thence through the Seaway following a transfer pattern identical to that of ore transported on the Great Lakes system. Seaway locks limit ore carriers to 25-foot 6-inch draft, 700-foot length, and 75-foot beam. Iron ore in transoceanic trade is carried in special bulk cargo ships ranging in carrying capacity from 25,000 to 70,000 long tons. Oceangoing iron ore cargo ships with carrying capacity over 100,000 long tons are being planned.

Iron ore from mines in the Southeastern, Northeastern, and Western States including Texas and Missouri normally moves all-rail to the furnaces, and 1 to 2 million tons annually is transported all-rail from the Lake Superior district. Less than 1 percent of the iron ore produced domestically is moved from mines to furnaces by truck.

Transportation costs of delivering iron ore from mines to the furnaces range from 40 to 50 percent of the value of the ore. In 1963, charges over the Great Lakes system from the Mesabi range to the Pittsburgh Steel district were $6.60 per long ton; and all-rail charges were $10.23 per ton.

RESEARCH

Since World War II, private industry has been heavily engaged in iron research, principally to develop ore dressing techniques for beneficiating the taconites of Minnesota, and the jaspilites of Michigan. The industry supports research laboratories, with a total annual budget estimated at more than $5 million. Total industry expenditure for iron ore and associated research is believed to range between $15 and $25 million annually. The Federal and State annual total is about $1 million.

The Minnesota State Mines Experiment Station at the University of Minnesota has been conducting a small but comprehensive iron-ore research program since 1911.

The Michigan Bureau of Mineral Research was established on the campus of the Michigan College of Mining and Technology in 1955, principally to conduct research projects applicable to the State's iron-ore resources.

The Bureau of Mines has had an iron-ore research program since establishment of Bureau stations at the University of Minnesota in 1917 and at the University of Alabama in 1921. Until World War II, the Bureau's program was conducted without urgency and only to develop basic scientific technical data to expand and develop the base of the country's iron-ore resources, and to encourage development of iron industries in new areas. During the war, the Bureau explored many iron-ore deposits. Since then, the Bureau has been concerned with more immediate problems of increasing domestic iron supply and of devising mining and ore-dressing techniques that would enable profitable exploitation of complex iron-ore deposits. A small hearth, low-shaft experimental blast furnace is operated at Bruceton, Pa., by the Bureau in cooperation with private industry to study material substitution and operating techniques applicable to conservation and development of the Nation's iron resources.

OUTLOOK

The iron ore industry will be a vital part of the expanding industrialization brought about by rising living standards and a growing population. New mines will be opened to share in the markets created by the iron and steel industries now being planned for the recently independent, less developed nations. Others will be opened to help supply the demands foreseen for industrial areas now in existence. Those mines producing high-grade, low-silica pellets or equivalent will tend to capture the world markets. When most of the existing blast furnace capacity using high-grade pellets is utilized, partially reduced agglomerates will tend to supplant the pellets. That is when more blast furnace capacity is needed, it will be obtained through use of partially reduced agglomerates in preference to building more furnaces.

Technology will continue to exert strong influence on the course of the iron ore industry. Except in unusual circumstances, iron ore will be mined in open pits from the large low-grade, easily beneficiated deposits. The trend toward larger equipment and automation of transportation and crushing plants will continue. Drilling and blasting practices in the taconite mines will improve but not at the fast rate of the last decade.

By 1970 essentially all iron ore produced for consumption by the industrialized nations will be beneficiated. The conventional gravity and magnetic separation and flotation ore dressing processes will be refined and used more in series or combinations to produce a higher-grade product with decreasing silica-alumina limits. Electrostatic separation and roasting to obtain iron minerals susceptible to magnetic attraction probably will be applied commercially within the next decade.

Pelletizing will continue to be the preferred method of iron ore agglomeration in the United States and will be used more in other countries, but it will not replace existing sintering plants. Partial reduction in conjunction with pelletizing will be applied increasingly. However, researchers eventually will find a method to bypass the agglomeration process so that fine grain concentrate can be used directly to produce iron.

General economic and political activities probably will have little effect on the structure of the domestic iron ore industry, but production and transportation relative costs will trend downward. Common market countries may regulate the iron and steel industries to some extent but, other than in Luxembourg and the Lorraine district of France, competition eventually will force establishment of a free iron-ore market in Europe.

The outlook for economic and political activities related to the world iron-ore industry is that the long-term trend in the price of iron ore in terms of constant value dollars will be downward, and that future government actions will not adversely influence the industry and in some instances will actually favor it.

Worldwide capacity to produce iron ore probably will continue greatly to exceed requirements. Nevertheless, many mining districts now supplying ore to restricted markets may not have capacity to supply all ore of the grade and quality needed.

Mine capacity is distinguished from probable production which is related to but not numerically identical to requirements. In North America mine capacity to produce high-grade agglomerates in the United States will increase steadily. The Lake Superior district will continue to be the principal source of domestically produced iron ore. The district's capacity to produce high-grade taconite pellets will reach 30 million tons annually by the late 1960's and 40 to 50 million tons by 1980. By then the district also will have capacity to produce 10 million tons of high-grade pellets annually from semitaconite or soft ores. The district's capacity to produce direct shipping ores and the conventional 51 to 60 percent iron-ore concentrate probably will decrease rapidly through the next 5 years, and may be only 5 to 10 million tons by 1980. Capacity to produce these conventional ores in the Lake Superior district will be fixed by the domestic steel industy's need for flexibility in output.

The Northeastern district including Pennsylvania probably will maintain capacity to produce at least 6 million tons of high-grade iron ore agglomerates annually until 1980, although new deposits will have to be developed to do so.

The Southeastern district's productive capacity probably reached bottom when most of the underground mines in the Big Seam of the Clinton formation were shut down in 1959. Capacity to produce 3 to 5 million tons annually more than likely will be maintained in the southeast through 1970, but unless technology develops, competition from foreign operations will close most of the mines within the next few years.

Iron-ore productive capacity in the Western district, which includes Missouri, will expand to keep pace with Western markets, probably reaching 14 million tons annually within 5 years. It is just a question of time before the large

low-grade iron resources of Arizona, Nevada, and Montana are exploited on a large scale. Even assuming no radical change in technology or in transportation costs, it is expected that at least one deposit in each of these States will be producing ore by 1975. If transportation costs can be halved, deposits in South Dakota probably will be exploited for the Eastern market.

Alaskan iron ore deposits may be exploited for export to Japan or for local use. In either case their impact on the world's iron ore industry will not be significant.

Accordingly, it is expected that United States iron ore production for internal consumption will be 80 million tons of 60 percent iron ore by 1970 and 92 million tons by 1980. In addition 5 to 10 million tons will be produced annually for the export market.

Canadian iron ore productive capacity without doubt will be expanded at a rate to supply all the iron ore the U.S. and Canadian markets will absorb. In addition, Canadian ore will be mined for export to both Asiatic and European markets. The Japanese probably will continue to buy ore from Canada at a rate commensurate with other trade between the two countries. Japan bought 1,545,000 tons of Canadian ore in 1962. Canadian producers will be at a cost disadvantage competing with South American and African producers for the European markets, but high quality, reliability, and preferential treatment by the British may enable the Canadians to maintain substantial exports eastward. Canada sold 2,850,000 tons of iron ore to European countries in 1962. Canada's capacity to produce high-grade iron ore probably will exceed 60 million tons per year by 1980. Actual output, however, may range substantially below the growth rate indicated by that figure.

Mexico will produce iron ore for its own needs but probably will not export significant quantities. Almost certainly, Mexican iron ore will not affect U.S. markets.

The outlook is for iron ore producers in South America actively to continue supplying ore to the United States, Japan, and European countries. The only readily apparent conditions that could prevent their doing so are political instability and confiscatory taxes. Large, easily mined, high-grade deposits, year-round moderate climate, and in most instances proximity to salt water ports give the South American producers an inherent economic advantage over most other producers.

Transportation probably will continue to be the bottleneck that limits iron ore output in the Minas Gerais district of Brazil. This situation may be alleviated within 5 years by a new rail line from the district to Rio de Janeiro. The outlook is for favorable government action to permit building of such a line. A new line, and enlarged capacity through the part of Vitória will increase Brazil's potential for iron ore exports to 30 million tons per year. Iron ore needs of the Brazilian iron and steel industry will not affect significantly Brazil's capacity to export ore.

Chile's iron ore productive capacity more than likely will remain above its own needs and ability to find markets. Export capacity could reach 20 million tons per year by 1980, but export shipments probably will not increase at a comparable rate.

Peru's iron ore productive capacity is expected to change very little in the next decade or two. Considering the planned developments in Australia and potential developments in the Western United States there is much doubt that there will be incentive for Marcona to install a new plant to obtain more production. Increased efficiency and minor plant additions may increase Peru's export capacity to 10 million tons per year. Output will depend on markets. The Peruvian iron ore industry should be competitive around the world; therefore, an aggressive sales policy could result in exports much higher than the estimated 10 million tons.

The Venezuelan iron ore industry may be on the threshold of a revolutionary technical change that will put it far ahead of its competitors in supplying merchant ore to the world's markets. The government has been asked to approve plans to lay a pipeline from the oilfields of Eastern Venezuela in the State of Anzoategui to the mines in Piar District of Guayana area in the State of Bolivar. The line is to transmit natural gas for use in an iron ore reduction plant to upgrade Guayana ore from 60 to 85 percent iron. The plans call for initial plant annual capacity of 1 million tons of finished product which can be increased readily to 10 million tons.

The natural gas reduction plans greatly enhance the outlook for the Venezuelan iron ore industry. The combination of inexpensive reductant and high-grade, low-silica ore favor a successful operation. An 85 percent iron bearing material with suitable physical properties and stability to stand long-distance transportation would make its own market if offered at prices competitive with the contained iron in pellets and high-grade ore.

Accordingly, it is expected that by 1970 the Venezuelan iron ore industry will have annual capacity to produce 10 million tons of partially reduced ore plus 10 million tons of high-grade ore and that by 1980 the production capacity for partially reduced ore will be increased to 20 million tons.

European iron ore mines, with the exception of those in the Soviet Bloc and on the Scandinavian Peninsula, in the future will not be as significant a source of ore for the European iron and steel industry as they have been in the past. The iron ore industries in Great Britain, West Germany, France, Luxembourg, Spain, Austria, Italy, and Yugoslavia in all probability will either remain static or decline in relation to the size of their cohabitant steel industries.

Iron mines in Sweden, Norway, and Finland do not compare favorably in inherent cost of production with open-pit mines in more temperate and tropical climates. Nevertheless, the iron ore industry of these northern countries will continue to produce on a large scale, although individual small mines may not be able to meet world competition. The outlook is for total mine capacity of 30 million tons annually by 1970 and 40 million tons by 1980.

Among the Soviet Bloc countries only the U.S.S.R. appears to have potential for a growing iron ore industry to serve a market that is demanding higher and higher grade ore. The need of the steel industries of Bulgaria, Czechoslovakia, East Germany, Poland, Hungary, and Rumania for quality raw material to increase output will probably make them part of this market. Thus the outlook for the iron ore industry of the Soviet Bloc is for the mines in U.S.S.R. to expand capacity to supply most of the needs of the Soviet satellites and for many of the low-grade mines of the satellites to close.

It is doubtful that Soviet Bloc ore will move outside the Bloc and probable that free world ore will be shipped into the Bloc. The quantity of free world ore entering the Bloc will be determined by trade agreements similar to those now existing between Brazilian and Indian mining companies and communist governments. Therefore, the iron ore and iron and steel industries in the Soviet Bloc countries will have little if any influence on free world trade in iron ore.

African iron mines are destined to assume a larger role in the iron ore trade of the world. Political stability and economic responsibility probably will be the prime factors influencing the direction of growth. The Liberian industry, judging by past government performances, is the most favorably situated to expand at a rate compatible with potential markets. By 1980 the industry should have capacity to produce 20 million tons per year.

The Mauretanian and Sierra Leone industries have established markets in world trade, and there is no reason to believe that internal circumstances will be altered sufficiently to jeopardize external relations. The industry of Mauretania probably will have iron ore productive capacity of 8 to 10 million tons annually, by 1980. That of Sierra Leone probably will have 3- to 4-million ton capacity.

Gabon has the resources to support a substantial merchant iron ore industry. The extent of development in capacity to produce iron ore will be dependent on the activity in the European steel industry and on government stability. If the government encourages free industrial enterprise through 1970, development of iron ore resources will be dependent on markets for iron ore then existing.

Guinea also has the resources to support substantial merchant iron ore industries, but the apparent course of its government makes it unlikely that private companies will invest the necessary funds.

India is the only Asiatic country expected to increase significantly its capacity to produce iron ore for export. Goa's capacity probably will remain around 6 million tons per year while capacity to produce for export in Malaya and the Philippines will decline. The iron ore industry of India will increase its capacity well in excess of domestic requirements and in addition will maintain capacity to produce 2 to 3 million tons annually more than its export market. The total capacity of the Indian industry is expected to exceed 30 million tons of iron ore per year by 1980.

There is not much doubt that an active, aggressive iron ore export industry will be developed in western Australia by 1970. Its size will be limited only by its competition around the world. Trade agreements with Japan and European countries probably will be instrumental in developing capacity to produce at least 5 million tons per year for export by 1970 which may be increased to 10 million tons per year by 1980. However, if markets can be found for the ore, capacity could reach 20 million tons or more per year by 1970 and 40 million by 1980.

Assuming that super ore carriers are built to minimize the ocean transportation disadvantage in supplying European markets that Australian iron ore producers will have with those on the east coast of South America and the west coast of Africa, Australian capacity to produce iron ore for export should reach 8 million tons by 1970 and 15 million by 1980.

Thus the integrated capacity outlook is that the principal iron mines producing for international trade, excluding those in Communist countries, probably will be able to produce 290 to 300 million tons of high-grade iron ore per year by 1980.

Barring a major war that restricts freedom of the seas, every industrialized nation seems as-

780–887 O—65——31

sured of an adequate supply of high-grade iron ore easily available for a price equal to or less than that now established.

The United States is assured of the iron ore it needs under practically any circumstance as long as the North America transportation system is left intact.

The outlook for the domestic industry has bettered each year since innovation of the taconite industry. This improving situation has been brought about by technologic advance and increasing knowledge. Thus the thesis that the best key to the future is record of the past provides assurance that the domestic industry will fluorish in the next decade with current research and development substantiating this outlook. More than likely producers of high-grade pellets will tend to capture the markets and the producers of partially reduced pellets will take over from them as all the excess blast furnace capacity for smelting standard pellets is utilized. Domestic iron mines are in an excellent position to be in the forefront of this pattern.

Figure 3 shows the U.S. iron ore supply 1940–64 and a forecast of the sources of supply and the rate of consumption 1964 through 1980.

The forecast was made on the basis of anticipated U.S. steel production, which was converted to iron in ore requirements assuming that 0.67 ton of iron from ore would be used to produce each ton of steel. This figure discounts the impact that basic oxygen converters, and continuous casting units could have on the scrap to hot metal ratio. Iron requirements were converted to iron ore assuming an average grade of 60 percent iron for both domestic and foreign ore. U.S. steel production was projected in accordance with the historical use of steel per capita, assuming that it would increase at the 1.6 percent compound annual rate forecast by the Bureau of Mines, for the growth rate of population and labor force. This projection then was modified by consideration of technologic, economic, political, and social elements to forecast an iron and steel industry growth rate slightly above that expected for the U.S. population. The principal elements considered in making the forecast were—(1) better steel, (2) use of substitutes, (3) development of new uses, (4) imports of foreign steel, (5) expansion of foreign markets, (6) less expensive production methods, and (7) shifting U.S. population.

Better quality steel greatly slowed the rate of steel consumption in the last decade, but to the presently produced quality level this factor apparently has exerted maximum influence and therefore will not change the trend significantly in the future.

Use of substitutes and development of new uses for steel have by and large offset one another in the past. Now better quality steel and the steel industry's comprehensive, application research program should begin to bear fruit. New steel uses in the future probably will more than offset use of steel lost to substitutes.

Steel imports probably will exceed exports for the short term (5 years). The determining factor in the balance will be cost and quality. Here again quality and research favor the U.S. industry. Furthermore, the technologic advances and capital improvements of recent years and the probability of continuing advance and improvement put the domestic industry in an increasingly better competitive cost position. This leads to the conclusion that for the long term, steel exports will exceed imports, and the per capita output of steel will tend to increase accordingly.

Changing distribution of people in the United States will tend to cut down per-capita steel consumption because a larger percentage of the people will live outside the Chicago-Pittsburgh industrial complex where steel is the leading structural material.

Reinforced concrete and timber are preferred to steel in the Pacific Coast States, where the population is expected to increase 62 percent between 1960 and 1980, and the Mountain States, where it is expected to increase 55 percent. These increases are in contrast to the total expected population increase of only 37 percent.

These seven elements expected to influence the rate of steel production in large measure offset each other. However, time will tend to strengthen those elements that can increase steel output and weaken those that could decrease it. With this in mind the forecast of a growth rate only slightly higher than rate of population growth is considered conservative.

The forecast of iron ore requirements is a mean from which actual consumption is not expected to vary more than 15 percent, and the total supply—domestic production, plus imports, minus exports—is not expected to vary from actual consumption more than 10 percent. Domestic and Canadian mines producing high-grade iron ore pellets for consumption in the United States are in a position to maintain output near capacity. Those producing lesser quality will necessarily provide most of the flexibility needed to adjust supply to consumption. Iron ore imports from Africa and South American countries are not expected to vary significantly from the quantities shown on figure 3.

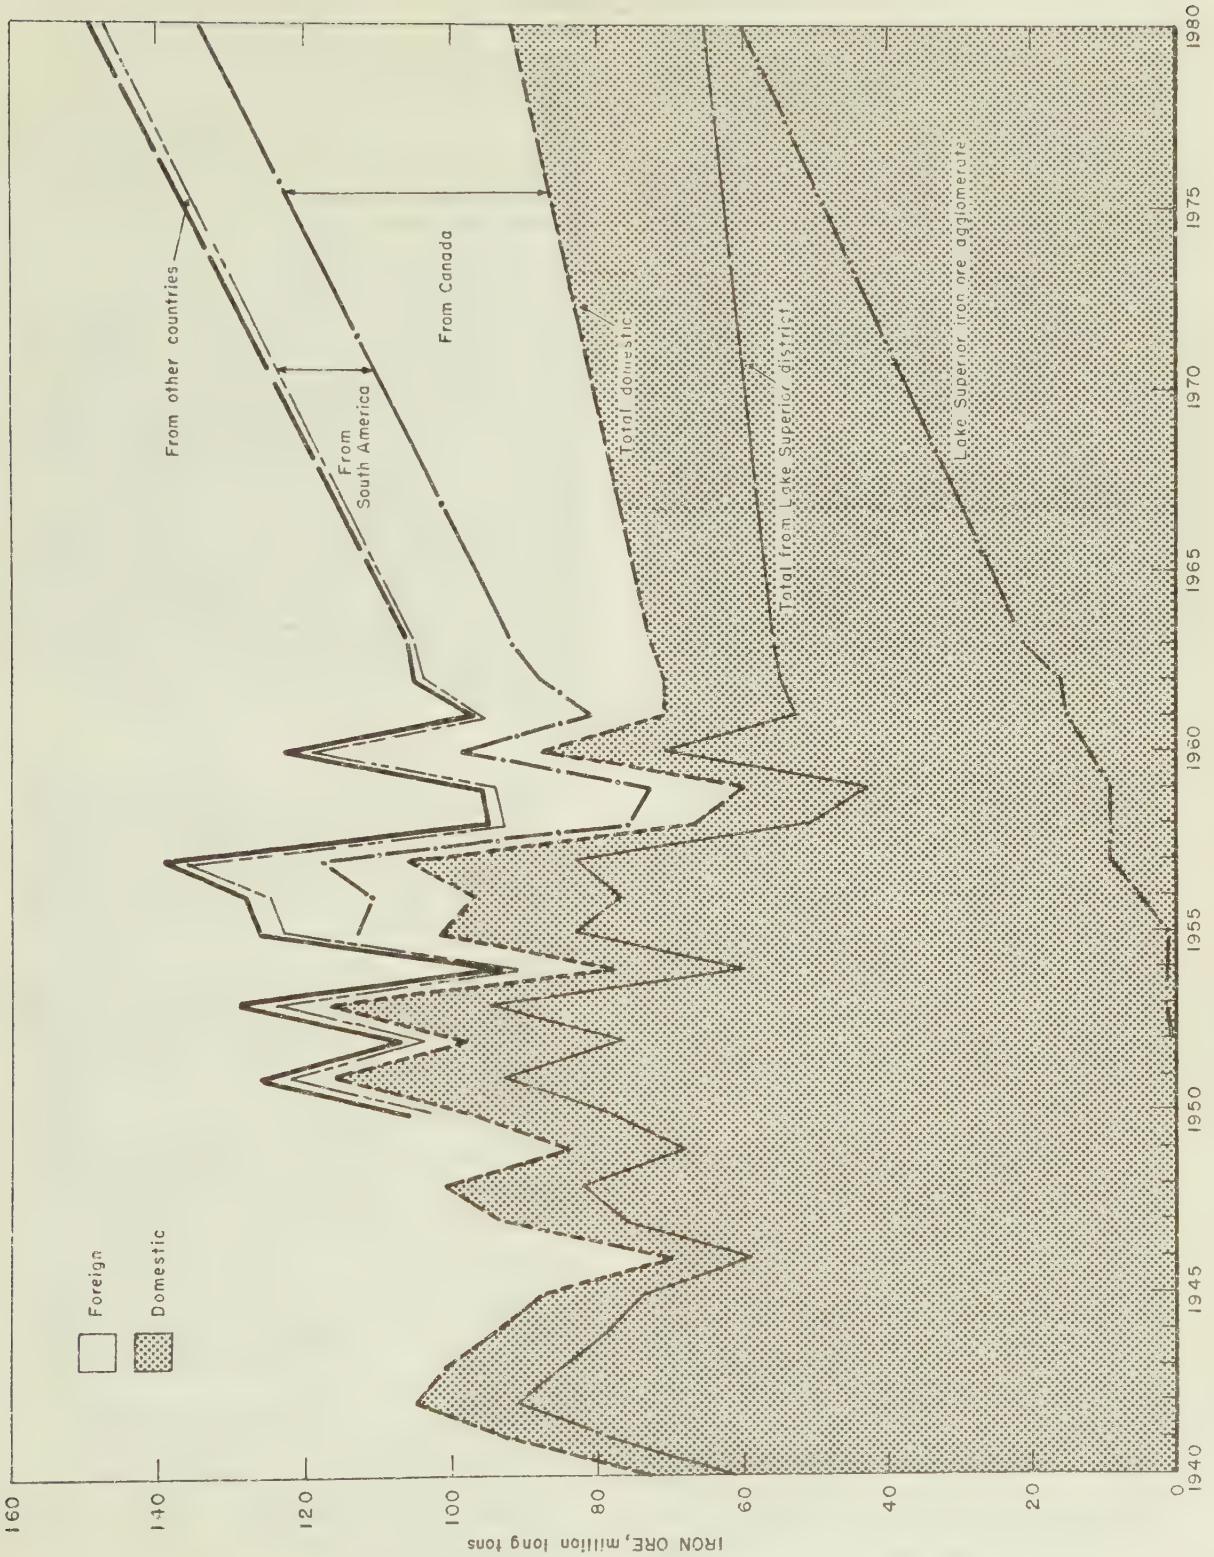

FIGURE 3.—Sources of United States Iron Ore Supply 1940–63 and Predicted Sources 1964–80.

PROBLEMS

The principal problem of the domestic industry is to meet both price and quality competition from foreign producers. It must do so if it is to continue to exist. The domestic industry has proximity in its favor, but all other elements of iron ore production favor one or the other of foreign operations producing iron ore for sale in the United States. This leads to many specific operating problems.

The iron formation in the Lake Superior region is exceptionally hard and fine-grained; consequently, both mining and grinding costs are high. Use of jet piercing equipment for drilling and scientifically designed blasting have been partial solutions to the problem, but the fact remains that mining costs in the Lake Superior district are not competitive with those in Canada.

Loss of the iron minerals not susceptible to magnetic attraction in taconite processing operations in Minnesota and some other districts is a problem. Researchers seem to be approaching an economical solution, but the problem is not yet solved.

More than two-thirds of the iron formation that is equal in grade to that being mined is not profitably amenable to any known method of concentration. Thus, inability to mine and process nonmagnetic taconite is a problem. The same is true of partially oxidized iron formation and soft hematite ores.

Transportation of iron ore is a problem, particularly from the Lake Superior district because there it is a seasonal operation. Not only are transportation costs high, but periodic operation forces consumers to maintain a large iron ore inventory. Agglomeration of fine-grained ore and iron ore concentrate is a solution to smelting these materials but because of the cost, it is not a completely satisfactory solution. Exploitation of titaniferous iron ore deposits is a problem because iron ores containing more than 1 percent of titanium cannot be easily smelted in a blast furnace without excessive operating difficulties and high fuel consumption.

KYANITE AND RELATED MINERALS

By James D. Cooper [1]

KYANITE and related minerals have been the basic raw materials used in the production of mullite since 1925. Mullite is an important refractory material, and its field of use lies between that of superduty fire-clay refractories and the extra-high alumina refractories. Small quantities of kyanite without calcination also are used in manufacturing glass, electrical and chemical porcelain, pyrometer tubes, and other ceramic products. Kyanite and the related minerals—sillimanite, andalusite, dumortierite, and topaz—all convert to mullite and siliceous glass at from 2,570° to 3,002° F. Mullite is stable and has a low coefficient of expansion up to 3,270° F, making it espécially valuable for refractories subjected to thermal shock. Mullite also may be produced synthetically from mixtures of bauxite, Bayer-process alumina, kaolin, and silica by sintering or fusion.

Until the early 1950's most mullite refractories were made from lump kyanite from India. Wartime circumstances led to greater use of domestic minerals, and postwar supply problems led to greatly increased commercial production of synthetic mullite. There are no known significant domestic sources of lump kyanite or related minerals. There are large domestic disseminated and placer deposits, but the concentrate from these is not as readily usable as the massive type for some applications. Three domestic companies produce concentrate.

The glass and metallurgical industries consume most of the kyanite and mullite produced.

Since mullite refractories are restricted to specialized applications, production is relatively small compared with that of superduty fireclay refractories, which cost substantially less but perform satisfactorily for many uses.

BACKGROUND

SIZE AND ORGANIZATION OF THE INDUSTRY

The domestic mullite industry, including production of kyanite, is relatively small, although its products are highly important for specialized uses. In 1963 about 135 people were employed in mining and milling kyanite, and probably not over 500 people were employed in producing synthetic mullite and manufacturing mullite refractories.

Initially (1917–24), synthesized mullite only was employed. The first synthetic mullite was produced by grinding mixtures of kaolin and alumina and calcining (sintering) at 2,850° F. Also from 1917 to 1924 synthetic mullite was produced by complete fusion of these minerals in the electric furnace.

About 1920 experimentation began with natural minerals. When calcined, the lump material yielded strong large aggregates of mullite crystals whereas the calcined concentrate yielded only fine-grained aggregates. No domestic massive kyanite was known at the time, but small deposits of massive andalusite and dumortierite were found in Nevada and California. Production of these minerals began in 1924 and continued until about 1945. By 1925 massive kyanite from Lapsa Buru in Kharsawan State, India (discovered in 1921) became available, and in 1944 massive kyanite from Kenya also appeared on the market. A topaz deposit near Naples, N.C., was operated from

[1] Commodity specialist.

1940 to 1950, but the material was used mostly as a substitute for fluorspar in steelmaking. Sillimanite production was reported for the first time in Australia in 1932, in India in 1938, and in the Republic of South Africa in 1946.

Concentrate from domestic disseminated kyanite is used as an ingredient in some sintered synthetic mullites, in ramming and mortar mixes, as the fine fraction in mullite brick and shapes, and in many ceramic products. In 1963 the kyanite producers were—Kyanite Mining Corp. at Baker and Willis Mountains, Va.; Commercialores, Inc., at Henry Knob, near Clover, S.C.; and Aluminum Sillicates, Inc., at Graves Mountain, near Washington, Ga.

The following firms produced synthetic mullite in 1963:

Firm and location	*Plant location*
The Babock & Wilcox Co., Refractories Division, New York, N.Y.	Augusta, Ga.
The Carborundum Co., Niagara Falls, N.Y.	Niagara Falls, N.Y.
Harbison-Walker Refractories Co., Pittsburgh, Pa.	Eufaula, Ala.
Norton Co., Worcester, Mass.	Huntsville, Ala.
H. K. Porter Co., Inc., Refractories Division, Pittsburgh, Pa.	Shelton, Conn.
Remmey Division of A. P. Green Fire Brick Co., Philadelphia, Pa.	Philadelphia, Pa.
The Chas. Taylor Sons Co., subsidiary of National Lead Co., Cincinnati, Ohio	South Shore, Ky.

DEFINITION OF TERMS, GRADES, AND SPECIFICATIONS

The kyanite and related minerals group of aluminum silicate minerals is comprised of kyanite, sillimanite, andalusite, dumortierite, topaz, and mullite. Kyanite, sillimanite, and andalusite have the same chemical formula but differ in crystal structure. Dumortierite contains some boron, and topaz is an aluminum fluosilicate. Mullite is obtained commercially by conversion of kyanite and related minerals at high temperatures. Synthetic mullite is made by sintering or fusing bauxite or alumina combined with kaolin or silica. Commercial specifications are lacking for the kyanite minerals and synthetic mullite. Consumers select material on the basis of chemical analyses, grain structure, and strength, and by determination of the Pyrometric Cone Equivalent (P.C.E.) usually by the method specified in ASTM Designation C–24.

National Stockpile Material Specification P–27, as revised in 1960, covers Indian lump kyanite and high-purity electrically fused synthetic mullite (*12*).[2]

[2] Italicized numbers in parentheses refer to the items in the list of references at the end of this chapter.

Although mullite refractories in general serve a temperature range higher than that of superduty fire-clay refractories and lower than that of alumina refractories, there is no sharp demarcation between classes of refractories. In addition, properties such as spalling characteristics, load-bearing capacity, and coefficient of expansion influence the selection of a specific refractory for a specific duty. Final selection is based on use-cost considerations, often without adequate data.

TECHNOLOGY

Geology and Mineralogy

Kyanite and related minerals are of metamorphic origin, and deposits of these minerals are restricted largely to highly metamorphosed areas, although some transportation away from the immediate area may occur. Because of their hardness and chemical stability, kyanite mineral deposits often form low ridges and hills. Most of the deposits of economic value are masses of kyanite or related minerals in quartzites, quartz and quartzite muscovite schists, or as residual boulders of kyanite rock and kyanite-quartz schist. Kyanite and sillimanite also occur in the heavy mineral fraction of beach sands.

Kyanite is an aluminum silicate which in the pure form has the formula $Al_2O_3 \cdot SiO_2$. Related minerals are sillimanite ($Al_2O_3 \cdot SiO_2$), andalusite ($Al_2O_3 \cdot SiO_2$), dumortierite ($8Al_2O_3 \cdot B_2O_3 \cdot 6SiO_2 \cdot H_2O$), and topaz ($Al(F \cdot OH)_2AlSiO_4$). All these minerals have the property, when heated to the proper temperatures, of transforming to mullite $3Al_2O_3 \cdot 2SiO_2$ plus SiO_2. For example, with kyanite, conversion begins at approximately 2,012° F and is completed at about 2,700° F (*12*). The mineral mullite rarely occurs in nature.

Mining

Deposits of massive kyanite and sillimanite, are largely on or near the surface and require hand mining only. Domestic disseminated kyanite deposits are mined by open-pit methods. Blasting is required and power shovels are used for loading. Beach sands are mined using power shovels or dragline excavators.

Milling and Heat Treatment

Massive kyanite is crushed and screened and ordinarily is converted to mullite by heat treatment before use in refractories. Sillimanite often is used in refractories without first being converted to mullite. Domestic kyanite ores are crushed, ground, and processed by flotation,

magnetic separation, and other means to produce kyanite concentrates suitable for use in refractory and ceramic products. The primary gangue minerals are quartz and mica, and the lesser impurities consist mostly of pyrite, iron oxides, and rutile (*9*, *15*).

When undergoing heat treatment, kyanite expands substantially, and for this reason it is precalcined for many uses. The expansion is an asset in some applications, such as mortars or where the expansion offsets the shrinkage of the bonding clay. All of the other kyanite group minerals expand very slightly under heat treatment but not enough to require precalcination. The boron in dumortierite and the fluorine in topaz volatilize during calcination. Sillimanite may be processed in the same manner as massive kyanite, but beginning about 1954, in England and Germany, some Indian sillimanite has been cut into blocks and shapes and used directly in furnace linings. A complete stack lining of sillimanite was installed in a steel blast furnace in England in 1959. The expansion during conversion to mullite is so slight that conversion under working conditions is accomplished without noticeable change.

A special problem in converting topaz to mullite during calcination is the safe disposal of the fluorine gas evolved. There are several processes that could accomplish this, one of which was tried on a pilot-plant basis by the Tennessee Valley Authority using topaz from the Brewer mine. The mullite was of good quality, but the calcium fluoride produced was of doubtful value as a salable byproduct (*14*). The cost of a degassing plant using any of the processes, however, would be too great for the tonnage of topaz in the Brewer mine.

Manufacture of Synthetic Mullite

Fused mullite is prepared in electric furnaces, and the materials used are the purest quality obtainable. Bayer-process alumina, produced principally from the Caribbean and South American bauxite, and high-purity silica sand are the principal ingredients. The final product is superior to that made from the best massive Indian kyanite. It is more costly, but is necessary for some special uses.

The raw materials for both types of sintered mullite are mixed thoroughly by ball-mill grinding, screened, pugged with water, and extruded in a column. The column is cut into lengths called slugs or dobies which are then sintered to produce mullite. The sintered material, or "grog", is crushed, ground, passed over a magnetic separator, and screened. To produce refractory brick and shapes, the grog is bonded and formed by power pressing, and the products fired.

Much of the high-temperature sintered mullite is made from materials comparable to those used for making fused mullite. The sintering is done at about 3,200° F. The product is at least equivalent to that obtained from the best grade of massive Indian kyanite and is perhaps somewhat less costly.

Low-temperature sintered mullite usually is made with a good grade of low-iron (about 2.75 percent Fe_2O_3 maximum) siliceous bauxite as the chief raw material. The sintering is done at approximately 2,800° F, thereby substantially reducing the processing cost compared with the high-temperature sintering method. Data that are available indicate that the quality of low-temperature sintered mullite is approximately equal to that produced from Indian kyanite.

USES

The manufacture of mullite refractories accounts for most of the kyanite and related minerals consumed annually, but nonrefractory uses are expanding.

Most mullite refractories are used as furnace linings in metallurgical and glass manufacturing furnaces. The remainder is used largely for kilns, kiln furniture, and saggers by the ceramic industry and in boilers. Small quantities of kyanite without calcination are used as a source of alumina in the manufacture of glass, electrical and chemical porcelain, pyrometer tubes, and in the form of kyanite concentrate to increase the alumina content of fireclays. Kyanite is used to improve workability, increase strength, and to compensate for firing shrinkage in floor and wall tile and other ceramic products.

BYPRODUCTS AND COPRODUCT RELATIONSHIPS

In Florida beach sand deposits mined for ilmenite, rutile, and zircon, the heavy fraction of tailings from milling operations consist principally of kyanite, sillimanite, and staurolite. Bureau of Mines research at the Tuscaloosa Metallurgy Research Center, Tuscaloosa, Ala., developed a method for producing a concentrate averaging 90 to 95 percent of a mixture of kyanite and sillimanite, with a recovery of 70 to 75 percent (*2*).

ALTERNATE MATERIALS

Specific substitutes for kyanite and related minerals are two types of synthetic mullite, fused and sintered. Bauxite, or alumina derived from bauxite is the principal raw material for synthetic mullite production. Secondary materials that may be used are kaolin and other clays, silica, and kyanite concentrate. For-

mulas and many processing details are trade secrets.

Alternates consist for the most part of superduty fireclay, high alumina, and pure alumina refractories. None of the alternate materials are entirely satisfactory from all standpoints, including initial cost, ultimate cost, service life, production rates, and quality of finished products.

RESERVES

Reserves of disseminated kyanite group minerals in the United States are large, but data are incomplete. Deposits presently exploited in three districts in the Eastern States contain a measured and indicated reserve of about 100 million tons of quartzose rock with 10 to 30 percent kyanite. These are—Farmville district, Va., 50 million tons; Kings Mountain district, N.C. and S.C., 40 million tons; and Graves Mountain, Ga., 10 million tons (*5*, *12*). Other deposits of kyanite-group minerals in quartzose rocks occur in the Eastern States and in California, Nevada, and New Mexico. Reserve data are lacking for all except the Petaca district, N. Mex., which contains an estimated reserve of 2 million tons of medium-grade ore (*5*).

Many hundred million tons of kyanite-bearing schists and gneisses containing about 10 percent kyanite are present in the Burnsville-Swannanoa belt of North Carolina. Large quantities of similar but somewhat lower grade material are present in Habersham and Rabun Counties, Ga. (*5*).

The Boehls Butte quadrangle in Idaho has large deposits of gneisses and schists which contain kyanite, sillimanite and andalusite that may have potential value. Bureau investigations in Idaho indicate that there are many tens of millions of tons of kyanite garnet schist containing 15 to 45 percent kyanite in the Woodrat Mountain area, and a like quantity of kyanite schist and gneiss of lower grade in the Goat Mountain area. An outcrop of kyanite schist with an estimated thickness of more than 50 feet and containing about 10 percent kyanite has been found in the Albion Range in Cassia County.

Other deposits of kyanite group minerals in metamorphosed argillaceous rocks occur in New York, Wisconsin, New Hampshire, Maine, and Massachusetts.

Titaniferous beach sands in Florida contain kyanite and sillimanite in addition to other heavy minerals. Although recovery of the kyanite group minerals is not considered economic at present, a reserve of about 12 million tons of contained kyanite is available for future use (*12*).

The only known reserve of massive kyanite in the United States is a 5,000-ton deposit at Willis Mountain, Va. (*12*).

The deposits of massive kyanite in India are the best known foreign deposits, having been worked since the 1920's. The kyanite belt in Singhbhum district, Bihar State, is 70 miles long, with local enrichments. The largest deposit is at Lapsa Buru at the western end of the belt. Recent reserve estimates are lacking, but production at Lapsa Buru has far exceeded a 1929 estimate of about 214,000 tons of surface boulder material, and production has increased in recent years. A later estimate indicated that there is about 750,000 tons of kyanite to a depth of 10 feet. The sillimanite deposits in the Kasia hills, Assam, contain about 2 million tons according to a recent estimate, which presumably includes deposits of disseminated mineral. Other significant deposits of kyanite group minerals occur in Mysore and Travancore.

The reserve of andalusite-quartzite at Semiz Bugu, Kazakh S.S.R. is estimated to be 72 million tons of rock containing 18 percent andalusite. Approxiately 50,000 tons of andalusite occurs in a placer deposit at Chaingt, eastern Siberia.

The known reserves in European U.S.S.R. occur on the Kola Peninsula. At Kiev, reserves of 54 percent andalusite ore in metamorphosed sediments total 3.6 million tons, and at Lovozero an andalusite-nepheline syenite deposit contains 200,000 tons of ore with 30 percent andalusite.

A reserve of several million tons of kyanite is reportedly available in the Wipp Valley of the Tyrol, Austria. In Bulgaria a deposit containing about 900,000 tons of kyanite was reported in the Rhodope Mountains.

At Boliden, Sweden, andalusite occurs in irregular bodies in altered volcanic rocks. The bodies are up to 35 meters thick and 170 meters long.

Kyanite group minerals occur in economic quantities in North Korea and South Korea. At Pyonggang-gun, Kangwon-do, North Korea, a kyanite deposit with 200,000 tons was known prior to the Korean conflict. There is a large deposit of kyanite-biotite-schist at Kangso-gun, P'yongan Namdo, North Korea. In South Korea actively mined deposits are at Ch'ongwon' gun Ch'ungch'ong-Bukdo and Sosan'gun Ch' ungchi'ong-Namdo. No reserve data are available. A large deposit of sillimanite schist containing 10 to 30 percent sillimanite was recently reported at Nonsangum, Ch'ung Ch'ong Namdo about 200 miles south of Seoul, and attempts to beneficiate the ore were underway in 1964.

Reserves of massive kyanite in the Murka-Loosoito belt in the Taveta district in Kenya

have been substantially depleted as has the reserve of massive sillimanite in the Pella area in Cape Province, Republic of South Africa. Large reserves of disseminated kyanite and sillimanite are still available. Deposits of andalusite in river sands in the Marico district, western Transvaal, Republic of South Africa are estimated to contain at least 400,000 tons of recoverable andalusite. A deposit containing 20 to 30 percent andalusite has recently been explored in northern Transvaal southeast of Pietersburg. The deposit is about 300 feet thick and at least 15 miles long. Elsewhere in Africa deposits are in Angola, Cameroon, Swaziland, and Malawai (formerly Nyasaland).

Kyanite group minerals occur in Australia, but known reserves are not large. Reserves of sillimanite at Broken Hill, New South Wales and Mt. Crawford, South Australia, where most of the production has been reported are probably less than 25,000 tons. Other deposits or occurrences of kyanite group minerals are in the Olary district, South Australia, and in Youmah and the Chittering Valley, Western Australia.

SOURCES OF STATISTICAL INFORMATION

Domestic production of kyanite and synthetic mullite is reported annually to the Bureau by domestic producers. Foreign production data are obtained by the Department of State and published by the Bureau of Mines. Import and export data are compiled by the Bureau of the Census and published annually by the Department of Commerce.

PRODUCTION, CONSUMPTION, AND TRADE

World production of kyanite and domestic production of synthetic mullite are shown in table 1.

Figures on domestic production of kyanite and consumption of kyanite and mullite are withheld by the Bureau to prevent disclosing individual company confidential data.

Imports and exports of kyanite and related minerals are shown in table 2.

[1] 1954 data known to be not comparable with other years.

Source: Bureau of the Census.

The only tariff effective in December 1963 on kyanite and related minerals was 15 percent ad valorem for calcined kyanite. There was no tariff on crude material.

STRATEGIC CONSIDERATIONS

Only Indian lump kyanite and electrically fused synthetic mullite are presently classified as strategic. In an emergency a conversion from use of Indian kyanite to synthetic mullite could be made in a relatively short time, but a few thousand tons of the Indian material is retained in the national stockpile to provide for the transition period. Production of the highest purity fused synthetic mullite is not great, and industry does not maintain large stocks. Large quantities of electrical power are required for its production, and in an emergency the power requirements for other important uses would increase. Therefore, a modest quantity of high-purity electrically fused mullite is included in the national stockpile. On June 30, 1964, inventories totaled 8,645 tons.

Production capacity for all types of synthetic mullite and domestic kyanite concentrate are adequate to supply emergency requirements. Small quantities of Bayer-process alumina would be required for the highest quality synthetic mullite. Domestic low-iron siliceous bauxite, with or without addition of domestic kyanite concentrates, could be used for all of the less exacting qualities of synthetic mullite.

GOVERNMENT PROGRAMS

Kyanite is on the list of minerals eligible for exploration assistance from the Office of Minerals Exploration, Department of the Interior. Under this program the Government will advance 50 percent of approved costs of exploration programs for kyanite.

PRICES AND COSTS

Kyanite prices as of December 1963 were as follows: Per ton, f.o.b. point of shipment, Virginia and South Carolina, 35-mesh, carload lots, in bulk, $44 to $45, in bags, $47; 200-mesh, in bags, carload lots, $53 to $55; imported, 60-percent grade, in bags, c.i.f. Atlantic ports, $76 to $81 per short ton.

Synthetic mullite prices are not quoted on the open markets as are those of kyanite but are subject to quotation from individual producers. The prices depend upon the type of manufacture, degree of processing, and specifications required by the individual consumer. In 1963 the average value of the mullite produced as reported to the Bureau was $120 per short ton. Special products are valued at several hundred dollars per ton.

TAXES

There are no special taxes imposed on the kyanite industry. Producers are granted a depletion allowance of 23 percent on domestic production and 15 percent on foreign production.

RESEARCH

Research on mulite was started by the National Bureau of Standards in 1917 (*12*).

Since 1924 the Bureau of Mines has conducted research intermittently on kyanite and related minerals (*16*, *17*, *19*, *22*). The effects of major impurities on the properties of mulite and the possible uses of the Florida beach sand tailings were investigated (*2*). Substantial research was done on the concentration of ores from Georgia and South Carolina sillimanite deposits (*10*) and later on Florida beach sand tailings (*23*). The Bureau investigated and reported on several occurrences of kyanite, sillimanite and topaz in the southeastern States (*10*, *11*, *15*, *18*) and presently is investigating occurrences of kyanite and related minerals in the Pacific Northwest.

The development of the technology of fused and sintered synthetic mullite is done almost wholly within the refractories industry. Very little research has been published.

OUTLOOK

The outlook for domestic consumers of kyanite, sillimanite, andalusite, and synthetic mullite has improved greatly during the past decade so that at present the United States is essentially independent of Indian and African sources of mullite-forming raw materials.

Synthetic mullite made from readily available raw materials now accounts for more than 80 percent of the strategic mullite used in the United States. This percentage should remain fairly stable during the next 5 years while the total domestic requirement for strategic mullite will probably increase about 5 percent per year. Production capacity for both sintered and electrically fused synthetic mullite is substantially in excess of actual production, and additional capacity is planned by some producers. Manufacturing processes for sintered synthetic mullite have been improved, and additional improvements are expected as research on mullite structure advances.

Until the early 1950's imported kyanite accounted for practically all of the strategic mullite used in the United States. In recent years imports amounted to only about 20 percent. Although imports should continue to supply a small part of the Nation's requirements, in an emergency synthetic mullite production could be increased easily to compensate for any reduction of imports.

Total free-world requirements for kyanite group minerals and mullite are increasing about 5 percent per year. This rate should be accelerated during the next 5 years by industrial expansion in underdeveloped countries, particularly India. Reserves and production facilities are adequate to meet the requirements.

There has never been a shortage of minus 35-mesh domestic kyanite concentrates which are used in mortar and ramming mixes, as the fine fraction in mullite brick and shapes, as an additive to increase the alumina content of fire clays, and in ceramic body mixes. The use of domestic kyanite will probably increase 8 to 10 percent per year until 1970.

New uses for mullite refractories have been proposed, and if adopted they could increase mullite requirements at a faster rate. The major potential new application proposed is for lining blast-furnace stove sections and other critical sections of blast furnaces. Metal-fiber-reinforced mullite has been successfully tested for use on the leading edges of wings for hypersonic aircraft.

PROBLEMS

The principal problem regarding mullite refractories is regional shortages of mullite-forming raw materials. In the Western States, mullite refractories or the raw materials used to produce them, are now shipped in. This increases the cost to such an extent that mullite refractories cannot be used for many of the purposes for which they are suited. Mullite-forming raw materials, if available locally at reasonable cost, could also be used to increase the refractoriness of low-grade or subgrade fire clays.

Another problem concerns the availability of domestic bauxite for use in manufacture of low-temperature sintered synthetic mullite. The best material for this use is siliceous bauxite containing not more than 5 parts per hundred of the combined impurities Fe_2O_3, TiO_2 and alkalies, of which a maximum of 2 parts per hundred can be alkalies (*22*). Short-term require-

ments can be met from known domestic reserves, but additional reserves need to be found for long-term requirements.

An important problem of long standing concerns the lack of adequate specifications for kyanite minerals and mullite. The only current published specification is the Government's stockpile Specification P–27–R, which covers Indian lump kyanite and fused synthetic mullite (*12*). Specifications are needed for the domestic kyanite-group minerals and the minerals used to make sintered synthetic mullite to enable proper appraisal of the numerous deposits which are not presently being exploited.

Testing methods are presently inadequate and are cumbersome, difficult, and time-consuming. Many commercial ceramic testing laboratories are not equipped to conduct complete evaluation tests for kyanite and mullite. Fast, simplified, low-cost testing methods are needed by refractories manufacturers and by Government and commercial testing laboratories.

There are no published use-cost comparison studies between mullite refractories and other refractories used in the same temperature range. Such studies would be valuable in promoting more efficient use of refractory raw material resources.

Economical beneficiation methods are needed for kyanite-group minerals in the Western States.

LEAD

By Donald E. Moulds [1]

LEAD was one of the earliest metals utilized by man because of ease of refining and fabrication and widespread occurrence in areas of ancient civilization. Man still utilizes lead for corrosion-resistant sheets, piping, and many other ancient applications, and, in addition, a host of new uses have been developed to maintain its position as a leading industrial metal.

Lead ore is produced in over 50 countries and refined in 37 countries. World trade in lead ores and metal is a significant factor in the economics of several countries having ore-producing and/or metal-refining capacity surplus to domestic needs for lead and are thus exporters to lead-deficient industrial nations. World production of lead was 2.8 million tons in 1963. Australia leads in mine production followed by the U.S.S.R., United States, Mexico, Canada, and Peru. The United States is the leading producer of metal followed by the U.S.S.R., Australia, Mexico, Canada, and West Germany. The leading consumers of lead, in order of importance, are the United States, U.S.S.R., West Germany, United Kingdom, France, and Japan.

U.S. mine production in 1963 was about 253,000 tons, or 9 percent of world production. Mine production supplemented by imports of concentrates and bullion provided a domestic refinery output of 395,000 tons, approximately 14 percent of world primary refined metal. Primary production further supplemented with secondary lead and imported metal supplied the U.S. requirements of 1.16 million tons of lead in 1963.

Demand for lead increased substantially in 1962–63, and a continuation of the upward trend is indicated to meet the rising industrial consumption, especially in the field of transportation. Research and development in the industrial field have resulted in new applications as well as improvements in techniques and products for the historical applications and have maintained lead's competitive position.

World reserve of lead in ore, currently estimated at 50 million tons, is being added to at a rate in excess of depletion by mining operations. New developments, notably in south-central Missouri and in Canada, promise major additions to reserves and production potential in the near future. The strategic position of lead in the United States is excellent in view of the domestic productive potential, large government inventories, and availability of lead from neighboring Mexico and Canada. The current outlook is for a short-term, through 1966, supply deficit until presently planned mine and smelter facilities provide the domestic production potential necessary to meet the long-term requirements.

The major problem of the lead industry is to maintain a supply of ore and metal in coordination with expanding world demand at prices that encourage growth in use of the metal. This problem has many facets—mineralogical, industrial, geographical, and geopolitical. The lead industry needs to expand in coverage, and detail world statistics on which to base industry appraisal of the total situation with relation to mine production smelter output and world requirements to alleviate imbalances and resulting market disruption.

BACKGROUND

Lead's uses in pipe, sheet metal, weights and solders, and as an ingredient in glass and ceramic glazes were known in various degrees by the ancient Egyptians, Phoenicians, Greeks, and Romans. The Phoenicians worked lead mines in Cyprus, Sardinia, and Spain. The famed lead-silver mines of Laurium, Greece, supplied the ancient Greeks with much revenue. The great quantities of silver that enriched Rome for

[1] Commodity specialist.

six centuries were derived from lead smelting-refining operations in Spain, Sardinia, and Britain.

Lead was mined and smelted in Virginia as early as 1621, and the discovery of lead in the Upper Mississippi Valley was reported in 1690. Various efforts were made by the French to establish lead-mining operations in what is now the southeast Missouri lead district, during the first part of the 18th century, but production was negligible. The shallow mines of the Upper Mississippi Valley were important sources of lead during much of the 19th century. In 1867, discoveries in southeast Missouri at depths of over 100 feet led to development there of one of the two most productive lead regions in the world. The year 1961 marked the 54th consecutive year in which southeastern Missouri was the leading lead-producing mining district in the United States; the lead was lost to Idaho in 1962 because of a long strike at the St. Joseph Lead Co.

Lead production in the United States was annually about 1,000 tons from 1801 through 1810 but increased progressively to about 13,000 tons of lead a year from 1831 to 1840, approximately 10 percent of world output. Missouri and Upper Mississippi Valley areas were the principal producing regions. Lead production from 1840 through 1870 was essentially at the same rate as in 1831–1840.

Completion of the first transcontinental railway in 1869 gave further impetus to the lead-mining industry. An era of prospecting followed that led to discovery and development of lead deposits at Eureka, Nev.; Bingham Canyon, Park City, and Big and Little Cottonwood Canyons, Utah; Leadville, Colo.; Cerro Gordo, Calif.; Bonne Terre and Joplin, Mo.; and in the Coeur d'Alene region, Idaho. Production increased sharply in the 1870's, and both mine and smelter production grew rapidly during the 1880's and 1890's. The United States became the world's largest lead producer in 1893, and for 1891–1900 production annually exceeded 200,000 tons, or more than 25 percent of the total world output. Production increased remarkably from 1900 through 1929. In 1900, mine production of recoverable lead totaled 270,000 tons, and by 1925 it was 684,000 tons—more than one-third of total world output.

The stock of refined and antimonial lead at primary plants continued to increase, as consumption of lead declined reaching 207,200 tons at the end of January 1962. Industrial activity in the United States resumed an upward trend in early 1962 and lead consumption has shown a substantial increase beginning in January 1962. A strike at the Missouri Mines of St. Joseph Lead Co. which began on July 27, 1962, and terminated on April 1, 1963, along with quota restricted imports necessitated a heavy drawdown of producer stocks to meet the increasing domestic requirements and by the end of June 1964, primary producer stocks had been reduced to 29,000 tons and consumers were experiencing difficulty in obtaining sufficient metal. Outside the United States, production and demand were essentially in balance in mid-1964, in contrast to the surplus existing in prior years.

Many new techniques to improve mining, milling, and smelting were introduced or gained wide acceptance in this period. These techniques included mechanized haulage underground, use of centrifugal pumps, wide spread use of froth flotation (including differential flotation) and the development of sintering devices to improve the structure and smelting qualities of the blast furnace feed. In 1919 recovery from scrap first exceeded 100,000 tons and became the important element of lead supply that it still is, comprising over a third of the U.S. total lead supply.

The United States has continued to be one of the world's leading lead-mining nations since 1929; but owing to increased requirements, beginning in 1939, imports of ores and metal have been required to augment domestic mine production and secondary metal recovery to meet the expanding needs of domestic industry.

The decades following 1940 were marked by fluctuating production and consumption resulting from World War II, post-war recession, Korean hostilities, and the following recession. Expanded world production necessitated by war demands was surplus to a peacetime economy, and thus the supply-demand balance was in continual flux. The U.S. market was especially attractive to surplus foreign production after the Korean war, and excessive imports in comparison to reduced consumption resulted in an unprecedented tonnage of lead in U.S.-producer stocks. In late 1958, the United States invoked import quotas on foreign lead ore and metal to reduce these stocks (*16*).[2]

SIZE, ORGANIZATION, AND GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

Lead ranked fifth in tonnage of metals produced in the world in 1963, following steel, aluminum, copper, and zinc in that order. The United States was the world's foremost producer of lead as ore and as refined metal from 1893 through 1956. In 1957, Australia gained first place in mine production, and in 1958,

[2] Italicized numbers in parentheses refer to items in the list of references at the end of this chapter.

Australia and U.S.S.R. both surpassed the United States; the estimated refined metal production of U.S.S.R. exceeded primary production of the United States in 1959 and again in 1962. The countries of the Western Hemisphere produced 32 percent of the 1963 mine output of the world.

There are approximately 90 primary smelters and refineries in 29 countries ranging in annual capacity from less than 1,000 tons to the 246,000 tons of the Port Pirie, Australia, smelter of Broken Hill Associated Smelters Pty., Ltd. The refined lead output of the principle six countries, United States, U.S.S.R., Australia, Mexico, West Germany, and Canada, was 60 percent of the world output, and that of the Western Hemisphere about 33 percent.

The U.S. primary lead industry is composed of about 500 companies engaged in mining, smelting and refining, and marketing lead. In mining, seven companies—the St. Joseph Lead Co., United States Smelting, Refining & Mining Co., the Bunker Hill Co., American Smelting & Refining Co., the Eagle-Picher Co., The Anaconda Company, and National Lead Co.—produce more than 65 percent of the domestic output. The first 6 of these companies own the 10 primary lead smelters and refineries in the United States, and the National Lead Co., with American Smelting & Refining Co., operates secondary smelters having almost 50 percent of the total U.S. secondary capacity. The same seven firms together with American Metal Climax, Inc., and C. Tennant Sons & Co. (sales agents for important foreign producers) are leaders in competitive lead marketing, and all the companies, except United States Smelting, Refining & Mining Co., the Bunker Hill Co., The Anaconda Company, and C. Tennant Sons & Co., have lead mines abroad.

The secondary lead industry constitutes an integral part of the lead industry. Scrap lead is processed at both primary and secondary smelting plants to yield refined lead, antimonial lead and various lead alloys. In all, about 200 companies melt and smelt lead scrap, and the total lead recovered from scrap materials has exceeded domestic mine production since 1945 and in many years has exceeded production of primary refined lead from both domestic and imported ores.

About 96 percent of domestic mine lead output is from the area west of the Mississippi River. Nearly 60 percent of the lead mine production of the United States since 1875 has been from the Western States, chiefly Idaho, Utah, Colorado, Montana, Washington, Arizona, and California. The most important western districts or regions are the Coeur d'Alene, Idaho; West Mountain, Utah; Summit Valley (Butte), Mont.; Metaline, Wash.; and Upper San Miguel, Colo.

The remaining mine production comes predominantly from the West Central States with minor amounts from the Eastern States. The southeastern Missouri lead district has been the leading producer of lead in the United States since 1909 except for 1962 when production was curtailed by a strike. Geographic distribution of the lead industry on a world basis is shown in detail in the world lead production tables 12 and 13.

DEFINITION OF TERMS, GRADES, AND SPECIFICATIONS

Lead is a metal element, chemical symbol Pb; group IV and series 9 of the periodic system; atomic number 82; chemical atomic weight 207.21; stable isotopes 204, 206, 207, and 208; and radioactive isotopes 209, 210, 211, and 214. It is a soft, heavy metal, malleable but only slightly ductile. The specific gravity is 11.35 for cast lead at 20° C. The melting point is 327.4° C and the boiling point about 1,700° C at 760 millimeters pressure. Lead is the ultimate decomposition product of certain radioactive disintegrations; that from uranium has an atomic weight of about 206; that from thorium, 208.

Refined lead is marketed for use in the following seven grades: Corroding, chemical, acid, copper lead, common desilverized A, common desilverized B, and soft undesilverized. Specifications for these are given in table 1.

Large quantities of lead are marketed in various lead- and copper-base alloys. The lead-base alloys are roughly classified into bearing alloys, solders, type metals, low melting alloys, and the numerous antimony or hard lead alloys. The copper-base alloys containing lead are various grades of leaded brasses and leaded bronzes.

Secondary lead is lead derived from salvage of wornout end-product items, such as battery plates, cable covering, pipe and sheet, which are collected, remelted, and refined in secondary smelters to produce refined lead or various lead-base alloys.

[1] Corroding lead is a designation that has been used for many years in the trade to describe lead which has been refined to a high degree of purity.
[2] Chemical lead has been used for many years in the trade to describe the undesilverized lead produced from southeastern Missouri ores.
[3] Acid lead is made by adding copper to fully refined lead.
[4] Copper lead is made by adding copper to fully refined lead.
[5] Common desilverized leads A and B are designations that are used to describe fully refined desilverized lead.
[6] Soft undesilverized lead is used in the trade to describe the type of lead produced from ores of the Joplin, Mo., district.

TECHNOLOGY

Geology

The common lead minerals are galena (lead sulfide), cerussite (lead carbonate), and anglesite (lead sulfate). Galena is the most abundant lead mineral found in deposits that have been exploited in the United States. Galena is commonly associated with zinc, silver, gold, and iron minerals. However, in a few districts the ore is characterized by simple mineralization, with lead minerals present to the virtual exclusion of other ore minerals. A noteworthy example is southeastern Missouri, where the lead ores are usually composed of galena in an essentially nonmetallic gangue, with relatively little silver, zinc, copper, or other valuable metals present.

The more important economic deposits in the United States occur either as cavity fillings or replacements. The origin of the mineralization in the cavity filling and replacement deposits is similar. The theory that the mineral-bearing solutions were derived from a deep-seated igneous mass is most widely accepted today. Examples of the cavity-filling deposit are the San Juan, Colo., and the Upper Mississippi Valley districts. Replacement deposits are classified further as follows: massive, as at Leadville, Colo., and Bingham and Tintic, Utah; lodes, as at Park City, Utah, and in the Coeur d'Alenes, Idaho; disseminated, as in the Tri-State district and in southeast Missouri; and metasomatic, as represented by the Central district, New Mexico.

Prospecting and Exploration

Lead prospecting and exploration were relatively simple in the 18th and 19th centuries, when such important districts as southeast Missouri, the Tri-State, Upper Mississippi Valley, and Austinville, Va., were first brought into production. As the easily discovered, relatively shallow, ore bodies were depleted, it became necessary to employ new prospecting techniques involving careful geologic mapping of rock formations and structural features that control or may control ore deposition. Through intensive study the mining geologist and exploration engineer have increased their knowledge of the fundamentals of replacement, structural control, contact metamorphism, zonal distribution, structural barriers, wall-rock alteration, oxidation, and tectonics both before and after ore deposition and are utilizing this knowledge in guiding prospecting and exploration. Utilizing geophysical (*17*) and geochemical (*7*) techniques, largely pioneered in petroleum exploration, geologists and engineers have worked intensively seeking anomalous conditions indicative of conditions favorable to economic mineralization. These techniques have recently been used with much success to find anomalies that lead to ore discoveries in the Little River area of New Brunswick, Manitouwadge area of Ontario, and southeast Missouri.

Mining

Lead deposits amenable to open pit methods are uncommon but have found limited applica-

tion in the Tri-State district and Washington and more recently at Santander, Peru. Underground methods employing either open or supported stopes are used in most lead mines. Underground stoping includes block caving, room-and-pillar with and without rock bolts, shrinkage, cut-and-fill, and timbered stoping methods.

Improvements in mining practice in the past 40 to 50 years have been based largely on the development and extensive use of power equipment. Power shovels, scrapers, and mucking machines have replaced hand loading. Transportation also has undergone great changes; hand tramming and mule power have been replaced by motor trains operating on heavy-gage track. More recently trackless mining, which utilizes electric- or diesel-powered units, is finding wide usage in the lead and lead-zinc mines of Washington, the Tri-State (*4*), the Upper Mississippi Valley (*1*), and southeast Missouri (*3*, *8*). Mechanization is well adapted to the high backs, single-level mines that characterize so many of the lead and lead-zinc replacement ore bodies.

Other changes in equipment that have done much to improve mine output per man-shift include electric cap and floodlights at working faces, improved ventilation (including air conditioning), more efficient pumps, and powerful, lightweight rock drills using alloy steel or tungsten carbide bits.

Milling

Simple lead ores, such as coarsely disseminated lead or zinc-lead minerals occuring with a low-specific gravity gangue, are treated in heavy-medium equipment, jigs, and on tables after being crushed and rolled in closed circuit with screens or classifiers to give properly sized feed. Bulk or differential flotation of the slime products (*5*) or of a reground middling product completes the flowsheet. Ores of this kind are common in the mines of the Mississippi Valley and Eastern United States, but in some instances the ores are concentrated wholly by flotation.

Complex sulfide ores such as those of the Western United States consist of disseminated mixtures of fine-grained lead and zinc sulfides, usually accompanied by pyrite, copper sulfides, and gold and silver in a quartz or quartz-calcite gangue. Such ores may be complicated further by partial oxidation of the sulfides and presence of high-specific-gravity gangue minerals, such as barite, siderite, and rhodochrosite. The usual procedure on such an ore is to crush and grind in closed circuit with classifying equipment to a size at which the ore minerals are freed from the gangue minerals. When the ore minerals are interlocked, the usual practice is to make a bulk sulfide concentrate, followed by regrinding and selective flotation.

Low capital and operating costs have extended the field of the sink-float method to include pretreatment of certain ores, permitting upgrading of ores diluted by nonselective mining methods. Present milling practices result in recovery of 85 to 94 percent of the sulfide lead and up to about 88 percent of the oxidized lead. Sulfide losses consist largely of the extremely fine particles, and although much research has been done and improvements have been made in the recovery of fines the results are still unsatisfactory.

Smelting

Lead is recovered from its ores almost exclusively by smelting in blast furnaces or ore hearths employing carbon fuels. Ores or concentrates that contain few impurities may be reduced to metal in roasting hearths. Air is used to oxidize the sulfides and coke or coal to reduce the oxides. The ore hearth practice is followed at Galena, Kans., smelter, where (Newman) roasting hearths are used primarily in manufacture of lead oxide. The same process is employed at the New Broken Hill Smelter of Rhodesia, but is being replaced by blast-furnace methods.

In preparing the charge for blast-furnace smelting, the sulfur in the ores and concentrates is removed by a roasting-sintering process, usually on a Dwight-Lloyd sintering hearth (*10*). The sintering equipment eliminates most of the sulfur and produces a blast-furnace feed of desirable characteristics from the mechanically mixed concentrate, undersized sinter particles, and byproduct dusts and fumes collected in the smelter. Normally the charge to the lead blast furnace consists of lead sinter, coke, fluxes (such as silica and lime), and some lead-bearing furnace byproducts (*13*). Air is blown through the charge burning the coke to CO and CO_2 and producing a temperature of approximately 1,400° C. The carbon monoxide formed and the hot solid carbon reduce the oxidized lead compounds to bullion, which is tapped from the bottom or crucible of the furnace. Any copper, iron, cobalt, or nickel present in the ore combines with sulfur in the charge to form mattes which are tapped from the front of the blast furnace for subsequent treatment. Zinc present in the ore accumulates in the slag. When such slags contain 6 percent or more zinc, they are retreated in slag-fuming furnaces to recover the zinc and any remaining lead. The lead bullion contains precious metals present in the ore and metallic impurities which are recovered in the

refining operation. The recent development by Imperial Smelting Corp., Ltd., England, has gained favor in the treatment of complex lead-zinc ores. The three products of the furnace are zinc metal, lead bullion, and matte. A furnace of this type is presently operating in England, Australia, and Rhodesia, and several are in construction or planned throughout the world (*12, 14*).

Lead recoveries at primary lead smelters are usually about 97 to 99 percent of the lead contained in the ore and offer a relatively small margin for improvement. Recent modernization programs center largely on charge preparation, roasting, dust collection, and material handling within the plants (*14*). Such programs have more than doubled the productive capacity of lead blast furnaces since 1925.

Refining

Lead bullion from smelters operating on the ores of the Mississippi Valley, termed "chemical lead," is pure enough for most commercial uses without further refining. Lead bullion produced from western and most foreign ore contains enough gold and silver to make extraction profitable. It also contains various base-metal impurities that must be removed before the lead is marketable for end use. The sequence of processes for softening and desilverizing lead bullion and the recovery of byproducts is subject to many variations in practice.

Softening consists of the removal of copper, tin, antimony, and arsenic in a drossing or refining kettle. The copper is removed by holding the bullion just above the melting point and skimming copper dross from the surface. Agitation, with addition of elemental sulfur, causes the remaining copper to rise to the surface as a black copper sulfide powder, which is skimmed off. After copper drossing, the temperature of the bullion is raised and the bath agitated to induce surface oxidation. The tin, arsenic, and antimony are oxidized, and the oxides (being insoluble in the bath) rise to the surface with some lead oxide, which is skimmed off. The softened bullion usually is desilverized by the Parkes process of stirring metallic zinc into the bullion. Gold and silver, in that order, combine with the zinc and the resultant alloys on cooling rise to the surface and are skimmed off as gold and silver zinc crusts. The zinc remaining in the lead after desilverizing is removed by vacuum distillation or with caustic by the Harris process. If bismuth above acceptable limits is present, the bullion must be refined by the Betts electrolytic process, as at Trail, British Columbia, and East Chicago, Ind., or be removed by the Kroll-Betterton process after desilverization (*13*).

USES

An unusual combination of physical and chemical properties has given lead a wide range of industrial uses. The most important of these properties are as follows: Softness and extreme workability, high specific gravity, desirable alloying properties, low metal cost and high recoverability, high boiling point and low melting point, good corrosion resistance, and impenetrability by short wave radiation (*2, 9, 11*).

The principal uses of lead are for storage batteries, tetraethyl lead, cable covering, paint pigments, building construction, ammunition, and various alloys, chiefly solder, bearing metals, and type metal. Two of the larger uses—paint pigments and tetraethyl fluid—are dissipative. The greater part of the lead used in other forms is recoverable and eventually returns to supply as secondary metal.

Lead is used in the form of pure metal as in calking lead, cable covering, weights, foil, and sheets. It is widely utilized alloyed with certain metals, principally antimony and tin, in varying quantities to achieve the desired hardness, strength, friction, and melting-point characteristics desired for the specific application. The more common lead-base alloys are—bearing alloys, type metals, solders, ammunition and terneplate. The principal alloys of lead and content of other alloying elements are listed in table 3. Lead containing 6 to 12 percent antimony and commonly called antimonial lead is used chiefly in storage battery grids. Fusible alloys having controlled melting points ranging from 96° to 47° C are eutectic compositions of lead and various combinations of bismuth, tin, antimony, and cadmium. These alloys have expanding use in fire protection systems, precision casting, forming, and numerous other industrial applications. Lead is added to some copper-base alloys as well as to aluminum and steel to improve machinability. Lead is an ingredient in some greases and wire-rope lubricants to lessen frictional wear in especially abrasive service.

Large quantities of lead are consumed in the production of litharge, red lead, white lead, lead chromate, and basic lead sulfate. Litharge is used principally in storage batteries in both the positive and negative plates, either alone or mixed with finely divided metallic lead. Smaller quantities are used in the manufacture of ceramics, lead chromate, varnish, insecticides, oil refining, and rubber. Red lead is

used chiefly in storage batteries mixed with litharge and metallic lead in the positive plates and in paints. White lead is used almost exclusively as a paint pigment. Basic lead sulfate is used extensively in leaded zinc oxide and as a stabilizer in certain plastics.

TABLE 2.—*Lead use pattern in 1963*

Use	Percent of total

An important but small use is for shielding against certain types of dangerous radiation, chief among these being gamma rays. Where space is at a premium and utmost radiation protection is paramount, lead is prescribed. Another advantage is that lead does not become contaminated and may be used continuously without becoming radioactive and emitting its own harmful rays. For this reason it is important that lead for shielding purposes be free of impurities, particularly those that may become radioactive upon exposure to high-energy radiation. The atomic reactors operated by the Atomic Energy Commission employ combinations of concrete, lead, cadmium, and space to protect operating personnel from all types of radiation, including alpha, beta, gamma, and neutron rays. The two last are particularly dangerous because of their ability to ionize matter and hence injure living tissue. Lead is particularly effective in absorbing gamma rays, whereas cadmium or a hydrogenous material, such as paraffin or water, is used to shield against neutrons; but since gamma rays are emitted when neutrons are absorbed, it is necessary to stop the gamma ray with lead shielding. Lead containers used in handling and shipping radioactive isotopes at the Brookhaven National Laboratories total over 1,000 tons.

Of the chemicals containing lead, tetraethyl lead is the most important. Tetraethyl lead is a colorless, heavy liquid with formula $Pb(C_2H_5)_4$ and containing 64 percent lead. It is the active ingredient of the principal antiknock compounds added to gasoline to improve their antiknock qualities and efficiency. Premium gasoline for automobiles may contain 2 to 4 cubic centimeters of tetraethyl lead per gallon (about 3 grams of lead) while most other gasolines contain up to 1.5 cubic centimeters per gallon. The improved efficiency of gasoline as a result of this additive results in an economy in the quantity of fuel used.

BYPRODUCTS AND COPRODUCT RELATIONSHIPS

About 60 percent of the U.S. mine production of lead is mined as a coproduct with zinc and from this mixed ore in addition to the lead and zinc, important quantities of byproduct silver, gold, copper, cadmium, antimony, bismuth, arsenic, and tellurium are recovered. Although most of the zinc and sometimes the copper occurring in complex ores are differentially concentrated, the lead concentrate produced commonly contains zinc and copper, as well as the other byproduct metals listed above. These are recovered in lead smelting-refining. In fact if it were not for the association of precious metals, bismuth, antimony and some other elements with lead ores and recovery in the late stages of lead refining at a comparatively low additional cost, the world supply of these metals would be substantially lower in quantity and higher in cost.

ALTERNATE MATERIALS

Alternate materials are available which provide to a varying degree the properties and characteristics required in the classic applications of lead. Substitution of these materials depends on industrial factors of price, availability, dependability, and workability as well as many secondary considerations.

In the storage battery industry, the largest consumer of lead, there are alternate combinations of materials used in specialized applications in preference to the lead-acid cell such as cadmium, mercury, nickel, and silver. These materials are, however, limited in quantity and certain electrical characteristics when compared with the automotive and industrial requirements for storage battery power. The fuel cell may supplant in some specialized uses the electrical energy function of storage batteries.

Lead in gasoline antiknock additives constituting the second largest application of lead in the form of tetraethyl and tetramethyl presently does not have an economical alternate. Nickel, as well as other metallics, can perform a similar function in high-impression fuels. These materials have not, however, other necessary characteristics to constitute a large alternate potential. Large-scale substitution of diesel or turbine engines using low-octane fuels for the high-compression gasoline engine offers

a future possibility of reduced gasoline additive requirements.

Cable covering, the third largest application of lead, is an application in which alternate materials have substantially replaced lead. Polyethylene and combinations of metallic and organic materials are used as moisture insulation in underground power and communication cables. Oil and gas filled steel pipe has substituted for lead sheathing in some installations. The chemical inertness and corrosion resistance of lead along with flexibility, long life, and low-temperature extrusion and bonding, however, maintains the desirability of lead sheathing for extremely corrosive applications.

The development of materials replacing lead in paint pigments has proceeded rapidly and in many instances, especially interior and house paints, lead has been completely replaced by titanium and zinc pigments. As a basic paint for rust and corrosion protection, lead base paints are still preferred.

In construction applications, lead is competitive with many alternate materials. Synthetic seals have substituted for calking lead and alternate methods of connecting plastic and cement-asbestos pipe have reduced the use of lead in plumbing. Stainless steel, titanium, plastic, and cement are alternate materials in corrosive chemical construction. Development of new materials and methods continue in radiation shielding, vibration dampening and soundproofing.

The use of tetraethyl for aviation fuel has been substantially reduced by the development of kerosine and low-octane gasoline-burning straight jet and turbojet engines. Catalytic reformed gasolines of high-octane rating and inherent antiknock qualities are competitive in automobile fuels. The only competing additive that appears to have use potential is tetramethyl lead, quite similar in lead content and manufacture to those of tetraethyl lead.

TABLE 3.—*Principal alloys employing lead as a primary ingredient*

Alloy	Typical use	Percent content of alloying element		
		Antimony	Tin	Other
Cable lead	Cable sheathing	0–1. 0		0–0. 1 Te, 0–.03 Ca.
Hard lead	Pipe and sheet	1. 0–4. 0		
6–8 percent antimonial lead.	High-strength pipe and sheet.	6. 0–8. 0

50–50 soft solder	do		50. 0	
Lead-base tin babbitt	Bearing metal	10. 0–15. 0	5–10	0–1.0 Ca, 0.009 Li.
Arsenical lead-base babbitt.	Heavy-duty bearing metal.	12. 5–15. 0	0. 75–1. 0	1.0–3.0 As.
Type metal	Type	2. 5–25. 0	2. 5–20. 0	
Fusible alloys	Low melting fuses		8. 0–97. 0	45–60 Bi, 5–40 Cd, Ag, Zn, and In.
Terne metal	Plating steel sheets		2–2.5 or 10.0–25.0	
Leaded brasses and bronzes.	Machined parts		1. 0–10. 0	66–88 Cu, 2–30 Zn.

SECONDARY SOURCES AND RECOVERY

The United States has a large reserve of recoverable lead-in-use. The quantity is estimated to be in the order of 4 million tons of recoverable lead of which about 1 million tons is in lead storage batteries, 2 million tons in power and telephone cable coverings, and over 1 million tons in railway car bearings, lead pipe, sheet lead, and type metal. This in-use reserve provided the secondary industry with scrap yielding an average of 462,000 tons of recoverable lead annually for 1959–63. Table 4 presents the statistics of secondary lead recovery in 1962 and 1963.

TABLE 4.—*Lead recovered from scrap processed in the United States, by kind of scrap and form of recovery*

[Short tons]

Kind of scrap	1962	1963	Form of recovery	1962	1963
New scrap:			As soft lead:		
Lead-base	44, 803	59, 577	At primary plants	1, 842	3, 741
Copper-base	5, 586	6, 094	At other plants	116, 626	130, 788
Tin-base	529	611			
Total	50, 918	66, 282	Total	118, 468	134, 529
Old scrap:			In antimonial lead [1]	229, 392	244, 797
Battery-lead plates	252, 593	272, 412	In other lead alloys	87, 243	92, 203
All other lead-base	124, 277	135, 844	In copper-base alloys	9, 019	21, 878

Tin-base	5	5			
Total	393, 284	427, 189	Total	325, 734	358, 942
Grand total	444, 202	493, 471	Grand total	444, 202	493, 471

[1] Includes 3,693 tons of lead recovered in antimonial lead from secondary sources at primary plants in 1962 and 7,672 tons in 1963.

RESERVES

Lead-ore deposits are widely distributed throughout the world with commercially significant resources in some 50 individual countries. The more important reserves are in Australia, Canada, China, Mexico, Morocco, Peru, South-West Africa, United States, U.S.S.R., and Yugoslavia.

Information on reserves at the individual mining operations is obscured by individually applicable factors of economic minability and confidentiality as well as the normal tendency to maintain exploration and development only to the extent necessary to replace the ore mined. Reserves are, however, being added by new discoveries and extensions of presently producing deposits generally at a rate in excess of the lead produced. Since 1950, prospecting, exploration, and development in Canada has indicated some 6 million tons of lead in lead-zinc ores in the Pine Point, Bathurst, and Timmins mining districts. Exploration and development in Ireland and Yugoslavia have added substantial reserves, and the new south-central lead belt of Missouri is indicated to be a major addition to the U.S. reserve. Australia, South-West Africa and Peru are expanding reserves at presently operating mines.

Considering these developments and prior estimates, the measured and indicated lead reserves of the world are 50 million tons, equivalent to some 20 years output at current world levels. The reserve of inferred lead in ore is undoubtedly as large or larger.

Of the measured and indicated lead reserves, North America has about 37 percent or 18.7 million tons. Canada leads with 9 million tons followed by the United States with 6 million tons and Mexico with 3.5 million tons. The 3 million ton reserve of South America is mostly in Peru with other reserves in Argentina, Brazil, and Bolivia. African reserves of 4 million tons are primarily in South-West Africa and Morocco, with Algeria also contributing. Australia has substantial reserves of 6 million tons in the Broken Hill and Mt. Isa areas. Eastern European reserves are estimated at 10.1 million tons, mainly in the U.S.S.R. but also in each of the satellite countries. Yugoslavia, West Germany, Italy, Spain and Sweden account for the larger portion of the 5.6-million ton reserves of Western Europe. Asian reserves of 2.6 million tons are divided among Burma, China, India, Iran, Japan, North Korea, North Viet-Nam, Turkey—with China, Japan, and Burma the major areas.

CONSERVATION

Lead is so nearly indestructible that conservation is relatively simple. Almost all lead used except that in chemicals (including tetraethyl), pigments, and galvanizing is nondissipative and, except for uneconomic collection of some products, will eventually be returned to the secondary smelters for reclamation and reuse.

SOURCES OF STATISTICAL INFORMATION

Statistics on domestic and world mine and smelter production, domestic consumption of lead metal and scrap, stocks, shipments, and smelter average sales price are collected and

published by the Bureau of Mines. These data are supplemented by shipment-by-use figures published by the Lead Industries Association and by refinery production shipments and stocks compiled by the American Bureau of Metal Statistics. The Bureau of the Census conducts a census of the mineral industry of the United States every 5th year. Such studies provide valuable general information on productivity and costs. The Bureau of the Census also reports monthly import-export data for the United States. The International Lead and Zinc Study Group and the Organization for Economic Cooperation and Development collects and publishes statistics on world mine and metal production, consumption, and stocks.

TABLE 5.—*Supply and distribution of lead in the United States*

[Thousand short tons]

Year	Supply					Distribution		
	Primary lead production from—		Secondary production	Imports of metal	Total	Consumption	Exports of metal	Total
	Domestic materials	Foreign materials						
1954–58 (average)	322	180	476	299	1,277	1,128	2	1,130

1963	240	155	493	227	1,115	1,163	1	1,164

PRODUCTION, CONSUMPTION, AND TRADE

U.S. mine production of primary lead in 1963 was about 253,000 tons, approximately 9 percent of the world production. Mine production supplemented by imports of concentrates and bullion provided feed for the domestic refinery output of 395,000 tons, approximately 14 percent of the world primary smelter production. Primary production was further supplemented with secondary lead output and with imports of metal to meet the U.S. requirement of 1.16 million tons in 1963. Table 5 lists elements of supply and distribution for 1954–63.

World production of lead during 1954–62 was well in excess of world requirements, and large stocks were accumulated by primary producers, especially in the United States (*18*). In 1958, the U.S. Tariff Commission found imports of lead and of zinc to be threatening economic injury to the domestic industry. The President, on September 22, 1958, imposed import quotas effective October 1, 1958, which limited unmanufactured lead-ores, concentrates, bullion, and metal to 80 percent of the average annual imports from foreign countries during 1953–57. These quotas have constituted the ceiling for lead imports for consumption except during 1961–62, when approximately 104,000 tons of refined lead was obtained by government barter transaction with Canadian and Australian producers.

Domestic lead consumption, after suffering a major recession during 1957–61, recovered substantially in 1962 and increased again in 1963. The major lead outlets, storage batteries and gasoline additives, are for transportation. The adoption of jet engines on a large percentage of commercial and military aircraft substantially reduced the lead requirements for air transport, but the increasing number of automobiles and trucks has increased consumption in gasoline additives to record level. The number of vehicles on the road and the distance traveled are a major determinate of lead consumption. Other outlets of lead are associated mainly with construction and maintenance and have shown less fluctuation over the years, although trending downward in quantity. In 1963, the U.S. consumption of primary lead including domestic smelter production and imports of metal for consumption was approximately 23 percent of world primary production. The details of U.S. consumption are shown in table 7 and table 8.

World trade in lead is primarily in the form of concentrates and metal. Countries producing ore in excess of smelter requirements, notably Peru, Republic of South Africa, Canada, Australia, and Bolivia, are suppliers to the industrial countries having negligible or deficient output in relation to smelting capacity such as the United Kingdom, Belgium-Luxembourg, West Germany, France, and Japan. Several countries, notably Mexico, Australia, Canada, Yugoslavia, and Peru, have smelting capacity in excess of domestic metal requirements and export metal to the industrialized countries. The United States is an importer of both lead concentrates and lead metal from all of the the previously mentioned countries. Com-

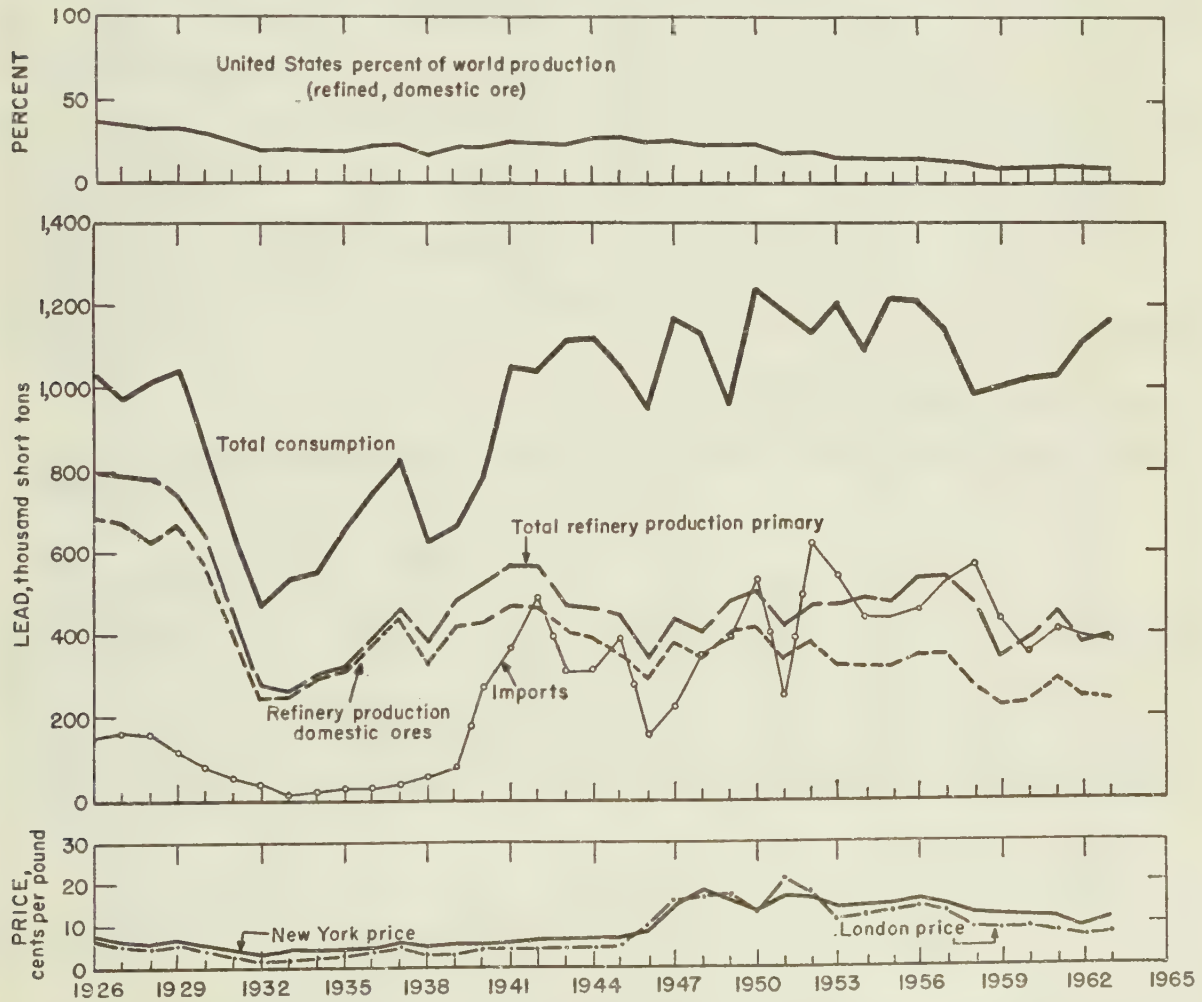

FIGURE 1.—Trends in the Lead Industry in the United States. Consumption Includes Primary Refined, Antimonial, and Secondary Lead, and Lead in Pigments Made Directly From Ore. Imports are Factored to Include 95 Percent of Lead Content of Ores, Mattes, and Concentrates and 100 Percent of Pigs, Bars, Base Bullion, and Scrap.

munist nation trade is principally between Communist countries, although varying quantities of lead concentrates are purchased and sales of metal made in trade with the free world (*2*).

For well over a century there has been a tariff on lead ranging from a low of 15 percent ad valorem to a high of 3 cents per pound, except for periods when such tariffs were suspended by act of Congress.

The statutory rate of duty under the Tariff Act of 1930 was 1½ cents per pound on lead content of ores flue dust, and matte and 2⅛ cents per pound on lead content of bullion, pigs and bars, antimonial lead, drosses and scrap. On June 6, 1951, pursuant to concessions granted in the General Agreement on Tariffs and Trade (GATT) these duties were reduced 50 percent to ¾ of a cent and 1 1/16 cents, respectively. The statutory rate is, however, currently applicable to imports from those communist controlled countries designated by the President.

New Tariff Schedules of the United States (TSUS) effective August 31, 1963, revised item designations but did not modify applicable tariff rates. Table 14 sets forth the schedules presently in effect.

TABLE 7.—*Lead consumption in the United States, by products*

[Short tons]

Product	1962	1963	Product	1962	1963
Metal products:			Pigments—Continued

TABLE 14.—*Unmanufactured lead and zinc articles rates of duty under the Tariff Schedules effective Aug. 31, 1963*

TSUS item number and article description	Rate under GATT	Statutory rate
602.10 All lead bearing ores [1]	0.75¢ per lb	1.5¢ per lb.
603.25 Lead dross [1]	1.0625¢ per lb	2.125¢ per lb.
624.02 Lead bullion [2]	1.0625¢ per lb	2.125¢ per lb.
624.03 Unwrought lead other than bullion.[1]	1.0625¢ per lb	2.125¢ per lb.

[1] Lead content.
[2] 99.6 percent of lead content.

SELF-SUFFICIENCY AND STRATEGIC CONSIDERATIONS

From 1925 through 1958 about 41 percent of the total U.S. supply of lead was from domestic mines, 34 percent from secondary sources, and the remaining 25 percent from imports. During 1959–63, under import controls, mine production amounted to 23 percent of the supply, secondary materials furnished 41 percent, and imports of lead metal proved 36 percent. In addition to heavy dependence upon imports of primary lead materials and metal since the beginning of World War II, the lead recovered in secondary operations was derived in part from imported scrap.

The United States is in a sound strategic position with relation to lead inasmuch as both the primary and secondary lead industry are well dispersed; the country is a next-door neighbor to Canada and Mexico, major lead-exporting countries; and because the strategic and long-term stockpile objectives have been met and substantial other quantities are held in the Government's supplemental stockpile. The Government holds in inventory a quantity of lead metal approximately equivalent to 1 year's consumption. On June 30, 1964, inventories totaled 1.4 million tons, of which 1.1 million was in the national (strategic) stockpile and 0.3 million was in the supplemental stockpile.

GOVERNMENT PROGRAMS

The Government regulated the lead industry during World War II and again in 1951–52 to provide adequate supplies for all essential purposes. In World War II measures were taken to increase imports greatly, expand or at least maintain domestic mine production, increase secondary recovery, decrease exports, and control consumption.

Lead was first recommended for stockpiling in May 1941, when the Office of Production Management proposed that the Metals Reserve Co. acquire 50,000 to 100,000 tons. Government stocks, built up largely from imports, increased monthly from 5,000 tons in August 1941 to a peak of 266,000 tons in April 1943. It was not until the latter part of 1944 that requirements necessitated continued withdrawal of large quantities of metal from the stockpile; by July 1945 the inventory had decreased to 65,000 tons. In the postwar period stocks were made available to consumers, and in 1948 the small quantity remaining was transferred to the national stockpile. In 1950, stockpiling was again undertaken to assure that adequate stocks would be available in the event of a major war. The quantity established as an objective was attained, and in March 1964 the scope of the stockpiling program was expanded when the President authorized the establishment of new long-term objectives. By early 1958 the new objective for lead was essentially met, and additional quantities obtained by the Commodity Credit Corporation under barter contracts were scheduled to be added to a supplemental stockpile division of the national stockpile.

Public Law 87–347 enacted on October 3, 1961, provides for subsidy payments to eligible small, domestic producers of lead and zinc ores and concentrates produced on or after January 1,1962, and prior to January 1, 1966. This program provides for payment of 75 percent of the difference between 14.5 cents per pound of contained lead and the average monthly market price for common lead at New York, for the month in which the sale occurred. Payment for zinc is based on 55 percent of the difference between 14.5 cents per pound of contained zinc and the average monthly market prices for prime western zinc at East St. Louis, Ill., for the month in which the sale occurred.

Through September 30, 1964, a total of 128 applications from 13 States had been received of which 62 had been certified and 3 were in process. Total disbursement for lead and zinc through September 1964 under the program was $2.09 million.

Under the Defense Production Act of 1950, as amended, the Defense Minerals Exploration Administration (DMEA) was authorized to grant loans up to 50 percent of approved costs on exploration programs for lead. Public Law 85–701, enacted August 21, 1958, provided the authority for the new Office of Minerals Exploration (OME) which took over the DMEA activities. Through December–June 30, 1962, when lead was removed from the list of eligible metals, DMEA and OME had entered into 289 contracts for exploration of lead (and/or zinc). The total estimated cost was $27.8 million of which the Government's share was $13.9 million. Lead reserves were developed in several areas as a result of the DMEA program. The

program was particularly effective in southern Missouri where important new ore bodies were found which may contain several million tons of recoverable lead and are now being developed.

The International Lead and Zinc Study Group was inaugurated in May 1959 to replace the United Nations Lead and Zinc Committee. Membership was open to governments of countries that were members of the United Nations or appropriate specialized agencies interested in the production or consumption of, or trade in lead and zinc. The Study Group was charged, as an autonomous intergovernmental body, with providing continuous, accurate information on the supply and demand position of lead and zinc and developments in trade on an international basis. The Study Group compiles and publishes monthly statistics on world production and consumption of lead and representatives of the 25 member countries meet annually to review the current situation, review special working group studies of specific problems and evaluate developments and trends in production, consumption, and world trade.

Pursuant to an Escape Clause investigation under authority of the Trade Agreement Extension Act of 1951, the U.S. Tariff Commission in April 1958, found increased imports of lead were causing serious injury to the domestic lead and zinc industry (*18*). On September 22, 1958, the President imposed import quotas on lead and zinc ores, intermediate smelter products and refined lead and zinc metal. The quota effective October 1, 1958, was established at 80 percent of the U.S. average annual import of these materials in 1953–57. The annual quota of 132,890 tons of lead in ores and 221,830 tons of lead metal and bullion was divided on a calendar quarter basis and major exporting countries to the United States assigned a quarterly quota for each category commensurate with imports during the basing period. Minor exporters were included in an "All Other" quota for each category.

PRICES

Lead prices since 1925 have ranged from an average annual low of 3.18 cents per pound, New York, in 1932 (8.32 cents in 1954 dollars) to an average annual high of 18.04 cents in 1948 (19.05 cents in 1954 dollars). During World War II, average sales price plus Government subsidy was about 8.50 cents per pound. Prices advanced markedly after the war and averaged 15.34 cents for 1947–50.

Following the outbreak of war in Korea in June 1950 lead prices attained a high of 17 cents in October. Ceiling prices were established for lead on January 26, 1951, at 17 cents per pound, common lead, New York. On October 2, 1951, the Office of Price Stabilization authorized sales at 19 cents per pound. Increased supplies and lower consumption brought about price reductions in 1952, 1953, and 1954. Early in 1954 consumer demand and a new program of Government stockpiling forced the metal price up to about 16 cents per pound by the end of 1955, at which level it remained until subsequent to April 1957 when cutbacks in consumption and announced cutbacks in stockpiling forced the price to 10¾ cents per pound, f.o.b., New York City on August 13, 1958. During the remainder of 1958 and until November 1, 1961, the price fluctuated between 11 cents and 13 cents per pound. The price decrease from 11 cents to 10½ cents on November 1, 1961, initiated a downward trend to bottom at 9½ cents on February 9, 1962, as heavy stocks and low demand softened the market. On November 1, 1962, an upward trend in price began as stocks decreased under improved industrial consumption and continued through 1963 and 1964 to reach 16 cents per pound on December 10, 1964.

TAXES

The percentage depletion rate for domestic lead mining is 23 percent. Foreign lead mining receives a 15-percent depletion allowance.

TRANSPORTATION

Lead ore containing sufficient lead to permit economic smelting without beneficiation is of small significance. The mined ore is normally concentrated at plants at the mine to minimize transportation expense. Exceptions are custom mills centrally located to serve several small, nearby mines wherein the economics associated with large concentrating plants compensate for the expense of truck haulage of the ore.

The cost of lead concentrate transportation from mill to smelter ranges widely dependent on distance. In 1960, the freight rate from Bonne Terre, Mo., to the nearby Herculaneum smelter was $1.25 per ton of concentrate. At the other extreme, the cost from Adler Creek, Idaho, to the Selby, Calif., smelter was $16.16 per ton. Transportation can thus represent up to 10 percent of the metal value of the concentrate and be a significant factor in cost of production.

Imported concentrates normally require several handlings via rail-boat-rail to the smelter. This transportation cost is a major factor of consideration, along with the other costs of smelting and market price of refined metal, by custom smelters in competitive purchase of foreign concentrates.

RESEARCH

Research is an increasingly important tool of the lead industry. Rising costs of production and marketing and desirability of maintaining a reasonable and stable price have sharpened competition on a world-wide basis and induced both producers and consumers of lead to undertake research projects that promise to yield short or long-term advantage for their products.

The Lead Industries Association founded in 1928 and now comprising some 70 producers and consumers of lead initiated a coordinated program of sponsored research, engineering assistance and information dissemination in the industrial application of lead and its compounds. Affiliated with the American Zinc Institute research program in 1958, the wide geographic scope of industry participation is indicated by the redesignation in May 1963 to the International Lead-Zinc Research Organization (ILZRO).

A significant development in industrial practice was the DM process for continuous casting of lead sheet devised by Broken Hill Associated Smelters and made public through ILZRO. Continuous extrusion of lead alloy cable sheathing is another recent development of importance. Numerous projects sponsored by ILZRO are currently in progress at industrial laboratories, educational institutions, and other facilities (*6*).

Many consumers of lead maintain extensive research facilities to develop new products and improve present products. Anticorrosion paints, vibration cushioning, and sound dampening are a few of the construction areas in which major advance has been made by industrial research, behavior investigation, and experimental application. Electronic research is involved in fabrication and circuitry of lead-compound semiconductors. Storage batteries and gasoline additives are being constantly improved by industry research.

Mining companies have emphasized research in recent years aimed at cost-reducing techniques for exploration, development, mining, and beneficiation. Improvements in trackless haulage, explosives, and automation devices have resulted in improved productivity in mine and mill operations. Technologic advances in geophysical devices have materially assisted exploration for previously hidden mineralization. Smelting procedures are being revised by adoption of the Imperial Smelting Process, to recover zinc metal and lead bullion simultaneously from complex ores.

Research by the Bureau is conducted on new techniques of ore extraction, beneficiation, and refining. Research and investigation directed toward the behavior of rock masses under stress and development of improved ground supports are of major significance. Mine safety research on mobile underground equipment has assisted in utilization of high-productivity equipment. Research in blasting techniques and utilization of nuclear energy in mining are other areas of interest. More effective and economic methods of beneficiating low-grade and complex lead-bearing ores and scrap have received much emphasis in metallurgical research conducted by the Bureau.

The Geological Survey conducts fundamental research relating to the genesis of ore bodies and the mechanics of ore emplacement. From these basic research projects, applied research projects are directed toward defining physical and chemical characteristics of ore bodies that may be used in field investigations of ore potential (*17*).

OUTLOOK

The two major outlets for lead are in storage batteries and gasoline additives which together account for over 50 percent of the total consumption of lead in the United States. Demand in these applications will grow in proportion to the number of cars on the road and the distance traveled. Since 1959 this combined use of lead in the United States has followed the 3.6 percent growth rate of GNP, and as these uses do not appear likely to suffer from technological substitution the growth is expected to continue.

Consumption of lead in the other combined historic uses chiefly in metal products and pigments, has shown a decline of less than 1 percent annually since 1959. Increases in some applications have been counterbalanced by declines in other fields. Intensified research in applications in the construction area are expected, however, to provide a modest growth element. The growth rate of lead consumption for all uses, amounting to about 1.75 percent since 1959, is thus expected to increase by about 2 percent annually to about 1.3 million tons by 1970.

Domestic mine production is expected to increase substantially under improved demand from expansion at presently producing mines and, chiefly, from new facilities presently planned, especially in Missouri. Domestic production is expected to achieve 400,000 tons annually by 1970.

Secondary lead recovered from scrap is governed by the recycling of scrap, over one-half

780-887 O—65——33

of which is contributed by wornout storage batteries. A moderate growth of 1.5 percent annually is envisioned to 525,000 tons by 1970 as this supply increases and price continues to remain attractive to scrap collectors.

The United States will continue to require about one-third of its total lead supply from foreign sources. Continuing high-level demand under presently limited imports and time requirements to develop domestic supply could result in a short-term, tight supply in the United States with resulting market disruption. World reserves of lead are adequate and indicated development of additional foreign supply sources, especially in Canada and Ireland, will provide a substantially larger output potential. The new developments both domestic and foreign along with presently operating mines and smelters are, however, expected to provide an ample long-term world supply of lead at a competitive price with the other metals.

PROBLEMS

The basic problem of the lead industry in past years has been the coordination of domestic and free world mine and smelter production to achieve a closer balance with consumption. This problem has many facets—mineralogical, industrial, geographical, and geopolitical. The coproduct association of lead and zinc in ore deposits, particularly in the Western United States and foreign countries, wide variations in grade-of-ore and production costs, general geographic separation of producing and consuming areas, and nationalistic as well as unstable political climate existing in some producing countries—all contribute to periodic surpluses and shortages in supply in comparison to demand.
